

This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

### Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

- + *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.
- + *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.
- + *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.
- + *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

### About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at <http://books.google.com/>

## PREFACE TO THE SIXTH EDITION.

---

ALTHOUGH the fifth edition of this text-book was very large, a year's time has brought so pressing a demand for a new one, that the author, in preparing it, has been obliged to confine himself to the most essential improvements and additions. There is an entirely new chapter on influenza, a disease which had almost been forgotten, when the last great epidemic brought it prominently to medical attention. Quite important changes and additions have been made in the chapters on cholera, malaria, diseases of the nose and larynx, syringomyelia, and diabetes. The appendix on poisons has also been considerably enlarged.

The author sends out this new edition with the wish that it may not only be of practical benefit to those for whom it is written, but may also add to their pleasure and interest in their vocation.

ADOLF STRÜMPPELL.

ERLANGEN, *May*, 1890.

## PREFACE TO THE FIRST EDITION.

---

IN the work which is now offered to the public I have made an attempt to give an account of our present knowledge in the field of the special pathology and treatment of internal diseases. This account, although brief, I have endeavored to make as complete as possible in regard to all important and certainly established facts. While everything hypothetical has been wholly omitted or only briefly referred to, I have tried, on the other hand, not only to enumerate the facts of clinical experience with sufficient accuracy, but also and especially to make the reader comprehend the development and the internal connection of the different morbid phenomena by constantly referring to the data of general pathological and anatomical research. In regard to treatment, the limits of our knowledge will often be apparent, but I believe that I have paid a sufficient regard to the needs of practice. In order to avoid repetitions, only a small number of complete prescriptions have been inserted in the text, but an abundant and well-arranged formulary has been added as an appendix at the end of the work.\*

Although in the composition of this text-book I have of course made very great use of the later literature of medicine, still the experienced reader will recognize in not a few places the results of the author's own experience and observation. These results are drawn from more than six years' active work in the medical clinique here, to the abundant material of which I have been fortunate enough to have access as assistant first to C. Wunderlich and then to E. Wagner.

ADOLF STRÜMPPELL.

LEIPSIK, 1 March, 1883.

---

[\* Owing to the differences between our Pharmacopœia and practice and those of Germany, it has been thought best to omit this appendix.—TRANS.]

## TRANSLATORS' PREFACE TO THE REVISED EDITION.

---

THIS translation is already used as a text-book or as a work of reference in some twenty-eight medical schools in America, and we trust that it will continue to meet with approval. After preparing this revised edition, the translators feel moved to express their admiration of the industry and carefulness as well as the sound judgment and great learning of their author. Scarcely a page has escaped some correction or addition; so that the work is thoroughly brought up to date.

THE TRANSLATORS.

Boston, *June, 1892.*

## TRANSLATORS' PREFACE TO THE FIRST AMERICAN EDITION.

---

THIS translation was made from the second German edition. After the work had been sent to the press in May, we learned that a third edition of the volume on nervous diseases had appeared in Germany. We therefore recalled our manuscript, and incorporated into it all the changes and additions that had been made in that edition.

We have tried to make the translation as exact as possible, but, in a few instances, we have taken the liberty of adding a word or a phrase to make the meaning clearer. With Dr. Shattuck's approval we have added a few foot-notes to the section on nervous diseases, embodying the results of investigations made subsequently to the appearance of the original.

In regard to the nomenclature of physical signs in diseases of the lungs, we have departed somewhat from the original in order to have our nomenclature conform to that proposed at the meeting of the American Medical Association in May, 1885, by the late Dr. Austin Flint, chairman of a committee appointed to prepare such a nomenclature at the International Medical Congress in 1881. This may explain certain unusual terms, such as "small râles."

We have not attempted to adapt the treatment to the United States Pharmacopœia. As a rule, when the preparation mentioned was described in Stillé and Maisch's National Dispensatory (second edition, 1879), we have made no comment. In other cases we have added the formula of the preparation either in a foot-note or in parenthesis. In a very few cases we have substituted an officinal (U. S. P.) preparation which was almost identical. As the metric system is not yet in active use, we have substituted for it approximate equivalents in the old system. We have considered it needlessly precise, however, to give the exact equivalents in tenths of a degree or hundredths of a grain. In every instance we have retained the author's figures in parenthesis, and we have added tables of weights and measures in an appendix. Measures of length have been left in the metric system.

In place of the original Fig. 106, page 763—specimens of handwriting in general paralysis, in German script, and in the German language—we have substituted other specimens selected from a large number kindly sent us by Dr. E. P. Elliot, first assistant at the Danvers Lunatic Hospital.

Our thanks are due to Dr. G. L. Walton, of this city, for his assistance at a critical moment in the work, and to other friends who have given us aid and encouragement during the progress of our labors.

THE TRANSLATORS.

Boston, November, 1888.

## EDITOR'S PREFACE.

---

THE appearance of a sixth German edition, and the demand for a revised edition of the American translation, seem to show that the high estimate formed of this work was reasonable.

In the present edition some notes have been omitted, others changed, and some new ones added. For most of the new notes in the section on Nervous Diseases I have to thank Dr. Knapp, one of the translators. His additions have been signed "K." For the others, with all sins of omission and commission, I alone am responsible.

FREDERICK C. SHATTUCK.

Boston, *September, 1892.*

## ACUTE GENERAL INFECTIOUS DISEASES.

### CHAPTER I.

#### TYPHOID FEVER.

(*Typhus abdominalis. Enteric Fever. Ileotyphus.*)

**Ætiology.**—According to our present views, the cause of typhoid fever must be sought in some specific, organized, pathogenic poison. The later investigations in bacteriology have apparently revealed what this poison is. Koch and Eberth were the first to point out a clearly specific variety of short, rod-shaped bacteria (bacilli), which appear in this disease alone. They take up the aniline colors. Koch and Eberth, and later W. Meyer, Friedländer, and Gaffky, found them in the intestine, especially in its lymphatic apparatus, and also in the mesenteric glands, the spleen, liver, and kidneys. The subjects in whom these bacteria were detected had died in the beginning or during the fastigium of typhoid fever.

The length of these bacilli (see Fig. 1) is about one third the diameter of a red blood-globule, and their breadth equals one third their length. Their ends are rounded off, and in their interior the formation of spores can sometimes be plainly recognized. They are found for the most part lying together in little clumps (foci of bacilli) in the organs. They have also been demonstrated in the dejections of typhoid patients, and sometimes in the blood taken from rose-spots.

That these typhoid bacilli are specific, is shown, however, as in the case of many micro-organisms, less by their external form than by their peculiarities, as observed in pure cultures of them. Gaffky, who first succeeded with such cultivations, found that the colonies of these bacilli, reared in a mass of stiff gelatin, are made up of very minute, brownish-yellow clumps, and that in their growth they are always limited to the spots where they have been implanted, and never liquefy the jelly in which they grow. The growth of typhoid bacilli upon the cut

FIG. 1.—Typhoid bacilli. Section of the spleen,  $\times 800$ .  
(After FLÜGGE.)

surface of boiled potatoes is also very characteristic. The bacilli cover the entire surface with a very thin though tough pellicle scarcely recognizable to the naked eye. Examined in water, the typhoid bacilli exhibit quite an active individual motion. The formation of spores takes place only when the temperature is between 86° and 108° (30°–42° C.), ceasing at lower temperatures.

Numerous attempts have been made to produce typhoid fever artificially by introducing pure cultures of the typhoid bacilli into the bodies of animals, but the results of these efforts have not yet proved perfectly harmonious. The main cause of the discrepancy is probably that animals are in general very slightly susceptible to the disease. At any rate, the attempts at artificial infection up to this date have proved successful only in cases when the animals subjected to the experiment (rabbits, guinea-pigs) have received large amounts of the typhoid bacilli directly into a vein or into the abdominal cavity (E. Fränkel, Simmonds), or when the bacilli have been introduced into the duodenum (A. Fränkel). Probably, however, we have here to do rather with the intoxication of the animals caused by the poisonous matters generated in the cultures of bacilli than with an actual infection, for the pathological changes of typhoid fever are but little developed in the animals, and the injected bacilli themselves appear to be for the most part destroyed within the body of the animal experimented upon (Flügge and Sirotoinin, and others). Attempts to produce the disease by mixing the dejecta of typhoid patients with the animal's food have thus far proved invariably unsuccessful. Probably the bacilli are immediately destroyed by the hydrochloric acid in the stomach.

Investigation of the ætiology of typhoid fever must consequently be directed to ascertaining in what manner and through what channels the specific typhoid bacilli penetrate\* into the human body, and what circumstances are then essential to their further development and to the display of their pathogenic properties. It must be confessed that the ability to answer these questions accurately is a goal from which we are quite distant.

It is almost universally believed that, as a rule, typhoid bacilli do not have any permanent, independent existence outside the human body. Often, however, the conditions essential to an abundant development of the bacilli arise in certain places, and thus make it possible for a greater or less number of persons to absorb the pathogenetic poison, and, as a result, to be attacked by typhoid fever. In this way occur the numerous greater or smaller epidemics of typhoid fever in contrast to the sporadic cases, which are likewise possible, and are not infrequent. If an epidemic of typhoid appears in a place till then entirely free from the disease, we must always refer it to an importation of the disease-germs, and seek their source in some previous case of typhoid. We must, therefore, take for granted that the poison of typhoid can in some way escape from the body of the patient into the outer world. If we believe this, we shall be sure to think, first of all, of the intestinal discharges as the source of infection. These discharges, as already stated, are known to contain the typhoid bacilli or their spores.

As to the exact manner of infection, views are still widely different. Up to the present time there are chiefly two contrasted theories, called, respectively, the "ground-soil" and the "drinking-water"† theories. According to the former, which is maintained principally by Pettenkofer and his pupils, the ground-soil is

\* Perhaps it is not useless once more to call attention expressly to the fact that typhoid fever can result only from an infection of the body with actual typhoid bacilli, and never through any other bacteria, through the products of decay and decomposition, tainted food, and the like; nor does there yet exist the slightest proof that typhoid bacilli can be developed from any other micro-organisms.

† Compare with what follows the statements concerning the ætiology of cholera, where the same disputed points are considered.

to be regarded as the chief place of development for the schizomycetic fungus of typhoid fever. Whether this will flourish depends chiefly on the condition of the soil (varying at different times and in different places), and this alone should explain all the peculiarities observable in the spread of the disease—e. g., that single houses, streets, or wards of a city should suffer. According to Pettenkofer, a soil that air and water easily penetrate—e. g., one made up of alluvial or detrital deposits—is most favorable for the spread of the disease, while a firm, rocky bottom makes its further development impossible; and, where this “tendency of the ground-soil” is wanting, the disease can neither be introduced nor, if brought in, spread any further; for, according to Pettenkofer, the typhoid poison is seldom if ever transferred directly from one person to another. The poison in the stools must first be changed by the soil before it becomes infectious. The “ground-air,” which is continually rising, carries the poison not only into the open atmosphere, but into the air of dwelling-rooms, and, being then inhaled, produces infection. We can thus understand why Pettenkofer regards typhoid fever as not directly contagious. The chief support of the ground-soil theory, beyond the results of comparing the character of the soil with the extent of the epidemics, consists in the proof which Buhl and Pettenkofer have given (taking Munich as an example) that a relation exists between the variations of the standing water in the soil and the frequency of typhoid cases. It appears that, when the water stands high (near the surface), fewer cases occur, and when it falls below the mean height cases are more numerous. This relation, which is said to hold true also for Berlin and some other places, is not yet, we may add, explained with certainty.

To be contrasted, or rather compared, with the soil-gas theory is the view held by many physicians, despite the vigorous protest of Pettenkofer, that drinking-water plays an important rôle in the origin of many epidemics of typhoid. In fact, in the case of numerous epidemics, whose extent bears an unmistakable relation to the water-supply, we seem perfectly justified in supposing that the typhoid germs are brought into the body by means of water used in drinking or otherwise. Even then we are by no means wholly to disregard the character of the soil, for the disease-producing poison—not to speak of direct pollution—is probably often communicated to the well-water from the soil. The possibility of this will be especially great if the wells are near drains or cess-pools containing typhoid discharges. In epidemics spread by drinking-water, the typhoid bacilli have lately been repeatedly found in the suspected water.

We believe the idea is continually gaining ground that no single “theory” can fully explain all the facts, and that the possibility of infection occurring in several different ways must be considered. Beside the possible inhalation of the poison, or the ingestion of polluted water, it may be that sometimes the disease is conveyed by food. For example, it has been remarked in England, and lately in Cologne, that the fever in certain epidemics was limited to individuals who had their milk from one common source. In such cases, however, the probable cause is not a disease in the cows, but a pollution of the milk or the milk-cans by water. It is as yet doubtful if animals can have typhoid fever; at any rate, all attempts at artificial inoculation have had a negative result. This fact makes it uncertain whether the illnesses which have been observed to follow the ingestion of the flesh of diseased calves (e. g., the epidemic of Kloten) are actually to be considered typhoid fever, although the pathological changes are said by Huguenin to be very similar to those found in typhoid. Finally, it seems very probable that persons who come into direct contact with typhoid discharges are thereby exposed to the danger of infection. Many deny this (*vide supra*), but it would explain why nurses and laundresses, who have to handle clothing soiled by the discharges of patients, are comparatively often attacked by typhoid fever.

Through the agency of dirty linen, utensils, etc., the poison may be spread even further.

[It is not probable that sewer-gas in itself is an exciting cause of typhoid fever. Especially in large cities typhoid dejections are constantly finding their way into the sewers, which afford all the conditions favorable to the further growth and development of the poison. If, then, the drainage of any house is defective, the seeds of the disease can readily gain access to the interior of the house and infect susceptible individuals.

One of the most instructive epidemics on record is that in Plymouth, Pennsylvania, a town of eight thousand inhabitants. In the spring of 1885 a disease, at first supposed to be of a strange character, broke out in the place, and, before it ceased, affected twelve hundred persons, causing one hundred and thirty deaths. It was soon found that the malady was typhoid fever, which arose from one case, briefly in this wise: In January, February, and March there was a case of typhoid in a house on a hill sloping toward a water-supply of the town. The dejections were thrown out on the snow, under which the ground was deeply frozen. On March 25th a sudden and great thaw occurred, the water did not sink into the ground, but ran immediately into the natural surface channels, and on April 10th the epidemic began. There were reasons, which it is not necessary here to detail, why the above source of water-supply was drawn upon to an unusual degree just at that time, but it has been shown that those who derived their water from other sources were spared by the disease. The original case came from Philadelphia.]

In almost all cases the intestine seems to be the actual gate of entrance for the typhoid poison into the human system. This is shown by the fact that in all cases which come to autopsy in early stages of the disease, the typhoid bacilli are mainly confined to the lymphatic tissues of the intestine. The typhoid poison (bacilli or spores) is probably swallowed, either directly with water or polluted food, or after being inhaled or in some other way introduced into the mouth. If not destroyed in the stomach, it passes on in viable condition into the alkaline contents of the intestine, and here finds the conditions essential to its further development. It penetrates at first into the follicles and Peyer's patches, and thence goes on into the mesenteric glands, the blood-current, the spleen, and other organs.

As in the case of most other infectious diseases, the occurrence of infection is dependent not only on outward conditions, but also on an individual predisposition. Details of the circumstances attending this latter are as yet not at all accurately understood. Even in the worst typhoid centers, where the possibility of infection must be universal, many escape the disease.

Age has an indubitable influence upon the liability to the disease. Typhoid is especially a disease of youthful, vigorous individuals, of fifteen to thirty years. Above that age it is noticeably less frequent, although cases do occur at sixty and even seventy years. Formerly it was often said that young children were never attacked; but this was because the disease was not recognized, for in reality it is only children under one year old who seem to be seldom infected. At a later age, cases are by no means rare.

Sex can not be shown with certainty to have an especial predisposing influence upon the frequency of typhoid fever.

Mental excitement and gross errors in diet seem to predispose to the disease. On the other hand, a certain immunity has been alleged to be given by many circumstances, especially pregnancy, the puerperal state, and other diseases already existing (tuberculosis, heart disease). Most of these statements are shown, however, by more extended experience, to be very doubtful. It does seem to be certain

that the occurrence of typhoid fever gives very probable though not absolute immunity against any later new attack.

Finally, it must be mentioned that the necessary conditions for an abundant development and conveyance of the typhoid germs are beyond doubt dependent on the season. According to statistics, most of the typhoid epidemics come in the months from August to November, while generally the number of cases greatly diminishes from December to spring.

**General Course of the Disease.**—Extended experience shows that, after infection with the typhoid poison has taken place, a certain time must elapse before the symptoms of the disease appear. The length of this time, the "stage of incubation," is, unlike that of many other infectious diseases, not perfectly definite. On the average, it lasts two to three weeks, sometimes less time, sometimes longer. During this period the patient either feels perfectly well, or has certain slight symptoms, to which he pays more or less attention, according to his individual susceptibility. These prodromata consist of languor, disinclination to exertion, anorexia, slight headache, pain in the limbs, etc. Often they last only a few days. Not infrequently the patients state afterward that they had felt the disease coming on for weeks.

The transition of the prodromata into the regular disease takes place sometimes so gradually that it is utterly impossible to take any one day as the first of the illness, in order to reckon from it its duration. It is usually, however, the first symptoms of a high temperature, chilliness, feverishness, and the accompanying increase in general discomfort, which allow one to fix, with at least some accuracy, the beginning of the disease. A decided initial rigor is certainly exceptional.\* After the fever begins, most patients soon take to their beds, although it happens often enough that the sick feel either unable or unwilling to give up, and keep on at work for days!

There have been manifold attempts to divide the whole course of the disease into separate periods. The most natural division seems to be into the three stages of development, height or fastigium, and decline (*stadium incrementi, s. acmes, s. decrementi*). Usually, however, physicians reckon according to the week of the disease. The first week corresponds to the developmental stage, the second, and in all severer cases the third as well, to the fastigium, the fourth (in light cases the third) to the decline. The course of the disease is very variable, however, and naturally there is the greatest diversity in the departures from this general plan.

In the first week, the initial period, the general symptoms augment rapidly. The patients become, in severe cases, very languid and feeble, have generally an intense headache, and complete anorexia, with great thirst. The fever, which is all the time gradually rising, is recognizable subjectively by alternating sensations of heat and cold, and objectively by the hot, dry skin, the parched lips, and the dry and coated tongue. The sleep is disturbed. For the most part there are no prominent thoracic or abdominal symptoms, except that at times there is a sense of oppression in the chest, or some cough. The pulse is quickened, sometimes even now dicrotic. There is often a temporary epistaxis. The belly is not much swollen as a rule, and but little if at all tender. There is generally constipation. Usually the spleen, even at this time, exhibits a swelling that can be easily demonstrated.

Generally the fastigium has begun before the end of the first week. The severe general symptoms persist or even increase. The fever maintains constantly a considerable elevation. The patients become more stupid. Often delirium

\* According to the representations of many authors, a marked initial rigor seems to occur rather often in some places. In Leipsic, and also in Erlangen, it is very rare.

appears, especially at night. In the lungs there is developed a more or less intense and extensive bronchitis. The abdomen becomes more swollen. On the skin of the trunk appear, generally at the beginning of the second week, a number

of small, pale-red spots, roseolæ. Instead of constipation, there is a moderate diarrhoea. There are daily about two to four soft, thin, bright yellow dejections.

The third week, during which in the severe cases the symptoms already mentioned persist, is the chief time of the numerous complications and of especial clinical events, about which we shall speak below at length. If the disease takes a favorable course, there comes at the end of the third week a decline of the fever; and then the general symptoms also improve as a rule. The mind becomes clearer, the patient sleeps better, and gains some appetite. The pulmonary and digestive symptoms abate, and convalescence gradually begins.

This short sketch of the course of the disease corresponds to most of the cases of medium severity. There are, however, besides these, so many forms and so many variations from the usual picture, that it seems almost impossible to enumerate completely all the events of typhoid fever. And besides, the separate epidemics vary in their general character according to the time and place of their occurrence. In many epidemics the cases run a peculiar course and have certain special complications not seen in others.

We will begin the presentation of the chief peculiarities by speaking of the course of the fever.

**Course of the Fever.**—Observation of the temperature in typhoid is so absolutely essential for the estimation of each individual case that no scientific physician ought to treat a case without regular measurement of the temperature. The measurements should be taken, if possible, in the rectum. Their frequency must of course be modified by circumstances, but it will probably be possible to have three or four measurements daily.

At night, especially if the patients are asleep, it is generally not requisite to take the temperature. A general idea of the course of the fever

can be gained only by representing the separate measurements graphically in a continuous "temperature curve."

The typical curve of typhoid fever (see Fig. 2) falls naturally into three or four divisions. The first division is the initial period, or the pyrogenetic stage, and is seldom observed, since at this time the patients are generally not yet under the doctor's care. The initial period of the fever lasts, as a rule, some three or four days, seldom longer; and during this time the temperature rises, generally by gradual steps, so that the morning as well as the evening temperature is each day  $2^{\circ}$  or  $3^{\circ}$  ( $1^{\circ}$ - $1.5^{\circ}$  C.) higher than on the day before. A sudden and considerable rise of temperature, such as occurs in many other diseases, is very rarely seen in the beginning of typhoid fever.

The second division of the curve represents the so-called fastigium, and corresponds to the height of the disease. During this time the fever presents, in most of the severer cases, the general character of "*febris continua*"—i. e., the spontaneous remissions of the fever seldom exceed  $2^{\circ}$  ( $1^{\circ}$  C.). Almost always the lower temperatures come in the morning hours and the higher in the evening. In cases of average severity the morning remissions touch  $102^{\circ}$ - $103^{\circ}$  ( $39^{\circ}$ - $39.5^{\circ}$  C.), and the evening exacerbations  $104^{\circ}$ - $105^{\circ}$  ( $40^{\circ}$ - $40.5^{\circ}$  C.). Temperatures which reach or exceed  $108^{\circ}$  ( $41^{\circ}$  C.) are seen only in very severe cases. Considerable morning remissions are always a favorable symptom, while morning temperatures of  $104^{\circ}$  ( $40^{\circ}$  C.) or higher generally show the case to be severe. The duration of the fastigium varies with the severity and obstinacy of the case. It may last only a few days or one and a half to two weeks; in violent cases still longer.

In many cases of slight or average severity the period of decline follows directly on the fastigium; but in severe cases there frequently intervenes another stage, which Wunderlich has graphically named the "ambiguous" period. The temperature curve becomes irregular and more variable. The morning remissions may be great, even reaching the normal, while the evening temperatures are often still very high. This stage has accordingly been termed the "period of the steep curves." It may be said that in general the longer a case of typhoid lasts the more irregular will be the course of the fever.

The last stage—i. e., in cases of slight or average severity the third stage, and in severe cases commonly the fourth—is the period of defervescence or recovery. The peculiarity of this period in typhoid fever is that the fall of the fever is never by crisis, but always gradually, by lysis. Commonly the temperature descends by degrees, so that on each new day the morning remissions as well as the evening exacerbations are  $1^{\circ}$  to  $2^{\circ}$  ( $0.5^{\circ}$ - $1^{\circ}$  C.) lower. The zigzag form of curve, in which there are of course very frequently slight irregularities, must be taken as the rule. The duration of the defervescence generally exceeds that of the initial period. It lasts five to eight days, often longer. It is not very seldom that in defervescence the morning remissions become from the first very marked, even reaching the normal temperature, while the evening exacerbations become daily less and less, until they too are not above the normal. A third form of decline is much less frequent, in which the morning remissions become every day greater, while the evening temperature persists for some days at about the same height. Several times we have seen the fever take on a tertian type during recovery.

To this outline must be added a number of observations of practical importance.

The initial period does not exhibit especial variations from the course we have stated. Its entire duration is bounded by certain relatively narrow limits.

The fastigium presents, as already mentioned, the greatest varieties in its duration. In light cases it is wholly wanting, so that these consist only of a period of gradually rising fever, and of a gradual defervescence almost immediately consecutive to the rise. The entire duration of such light cases is only one and a half

to two weeks. In other and tolerably frequent cases, which are often tedious, but still for the most part are light, the fever is not continuous, but remittent. We have seen in Leipsic, notably in the autumn epidemic of 1878, a number of cases where the fever was even perfectly intermittent during almost the entire illness, and where for two to three weeks afternoon elevations reaching  $104^{\circ}$  ( $40^{\circ}$  C.) or more daily succeeded normal morning temperatures. These cases had the general course of light attacks.

Various influences, not to speak of therapeutic interference, may produce a considerable temporary remission of temperature in the course of the fastigium. Such a remission sometimes occurs spontaneously from the seventh to tenth day of the disease. If a marked intestinal hæmorrhage occurs (*vide infra*), the temperature generally falls several degrees centigrade, and the less frequent instances of severe epistaxis have the same effect. If, in female patients, abortion or premature delivery occurs, we often observe a similar considerable fall of temperature, even without severe attendant hæmorrhage. Perforation of the intestine often causes the temperature to fall rapidly. At times the occurrence of mental disturbances effects a moderate though noticeable lowering of temperature. Those great and sudden depressions of temperature remain to be mentioned which are accompanied by a very small but exceedingly rapid pulse and general prostration. Every such collapse, if severe, is a most dangerous event, and demands prompt and energetic medical treatment (*vide infra*).

The occurrence of local complications, such as pneumonia or inflammation of the parotid gland, is generally accompanied by a considerable rise of temperature. The fever in such cases often becomes more irregular.

The period of defervescence departs most frequently from its typical behavior by being lengthened out into a "stage of retardation." The morning temperature is then generally normal, while in the evening slight or moderate elevations continue. The reason for this long continuance of the fever may frequently be found in some not yet completely healed local complication, but often no such lesion can be demonstrated. Then we are commonly inclined to surmise sluggish intestinal ulcers which will not heal, or trouble in the mesenteric glands, etc. This sluggish fever may continue for weeks. It is prone to follow severe cases, but lighter attacks, especially in elderly or feeble patients, may also take on this sluggish character at a relatively early period.

Entrance into complete convalescence is shown with far greater certainty by the absence of elevations of temperature than by any other single symptom. There sometimes come, however, temporary elevations of temperature during convalescence, following some error in diet, long-continued constipation, or mental excitement. In other cases the new fever depends on some local sequela, e. g., a boil or a glandular abscess. Often, however, the most accurate investigation fails to demonstrate a cause. Especially in the beginning of convalescence there sometimes comes a high fever, or even a rigor, which may recur several times, but soon gives place to a normal temperature. Generally no certain cause for these brief but decided elevations of temperature can be pointed out. Perhaps we might consider the possibility of some affection of the mesenteric lymph-glands. These sudden and great elevations have seldom any grave significance.

This new fever which we have just described is best termed recurrent fever-attack, in contrast with the proper typhoid relapse. That is, after typhoid fever has ended, the whole process may be repeated; and this occurrence is called a relapse. Particulars as to the behavior of the fever in such cases will be considered below, in connection with all the other peculiarities of typhoid relapses.

## PHENOMENA AND COMPLICATIONS RELATING TO THE SEPARATE ORGANS.\*

1. **Digestive Organs.**—We think it best to begin our consideration of the more special symptoms with the phenomena referable to the intestinal canal, for the reason that the anatomical changes in the intestine are pathognomonic. Indeed, these alterations may sometimes become of surpassing import in a clinical point of view, although in the majority of cases the intestinal symptoms are clinically not nearly so prominent as the general symptoms that result from the infection of the system as a whole.

The characteristic typhoid lesion of the intestine consists of an affection of Peyer's patches, most marked in the lower part of the ileum. In the first week the patches swell gradually (stage of medullary infiltration). The rest of the mucous membrane exhibits at the same time more or less marked symptoms of simple catarrhal inflammation. In the second week, necrotic crusts form on the surface of the patches, which are cast off in the third week, leaving behind the typhoid ulcers. Toward the end of the third week the ulcers clean up, and then in the fourth week, if the case takes a favorable course, the ulcers heal. Smooth scars are formed, often diffusely pigmented. Experience shows that these scarcely ever lead to stricture of the intestine. The same process also goes on in a greater or less number of the solitary follicles as well as in the Peyer's patches themselves. We may add that probably in lighter cases of typhoid (*vide infra*) there is often no actual ulceration. The swelling of the lymphatic tissue subsides in this case before sloughing occurs. We have already mentioned the occurrence of typhoid bacilli in Peyer's patches and the intestinal follicles.

The number and extent of the ulcers formed have no direct relation whatever to the severity of the case. Although very extensive lesions in the intestine are often found in cases that end fatally, yet, on the other hand, we observe fatal cases in which only a few ulcers are found in the intestine. In cases with extensive intestinal lesions we often see follicular ulcers in the colon as well as in the small intestine (colo-typhoid).

The clinical symptoms referable to the intestinal canal are, as we have said, prominent only in exceptional cases. In the beginning of typhoid fever there is usually constipation. This may last throughout the illness, so that the patients have but one dejection in every two or three days, or often none at all unless an enema be given. As a rule, a moderate diarrhoea begins during the second week. There are two to four stools, or sometimes more, each day. They usually have a characteristic bright-yellow color. On standing, they divide into an upper, cloudy, and quite liquid layer, and a lower layer composed of yellow, crumbly masses. They have generally an alkaline reaction, and upon microscopic examination they are found to contain, besides remnants of the ingesta and granular detritus, a few epithelial cells, round cells, many crystals of triple phosphate, and numberless bacteria. Pfeiffer and other investigators have been able frequently, although not invariably, to demonstrate the true typhoid bacilli in the dejecta by means of special methods of cultivation.

Severe diarrhoea (ten to twenty stools daily) is relatively infrequent. In some severe cases we have seen the stools take on a dysenteric character. The autopsy showed in these cases unusually severe lesions of the colon and a diphtheritic inflammation of its mucous membrane.

Gaseous distention affecting the intestine, and especially the colon, is very frequent, but in most cases it is not excessive. Indeed, severe cases of typhoid are

\* To avoid repetition, we have in what follows united a description of the anatomical changes with the presentation of the clinical symptoms.

observed in which the abdomen always remains concave. Marked tympanites is always an unpleasant complication. We saw one case, which ended fatally, with very great tympanites, in which the lesions were almost exclusively in the colon, and it was the enormous distention of its entire length which had so swollen the abdomen. The noise that can often be produced by pressure in the ileo-caecal region (gurgling) used to be regarded, but probably erroneously, as especially characteristic of typhoid fever. Abdominal pain is often entirely absent. Some patients, however, complain of abdominal pain during almost the entire illness. On pressure, the belly is generally somewhat sensitive, but the tenderness is seldom extreme. It is more apt to be marked when there is constipation. Often such tenderness is due to a participation of the peritoneum in the disease, even when there is no perforation (*vide infra*).

There still remain two symptoms of the greatest practical importance, both of which have a direct connection with the intestinal lesions: they are intestinal hæmorrhage and perforation.

Intestinal hæmorrhages in the course of typhoid are almost always due to the erosion of the walls of blood-vessels in connection with the formation and throwing off of the crusts of the ulcers. The hæmorrhages occur, therefore, most frequently toward the end of the second and during the third week. The blood pours out into the intestine, and is passed with the stools. Its amount may be small, or it may reach to one or two pints, or even more. Its color is generally rather dark. The later discharges are generally tarry. Liebermeister states that he has observed intestinal hæmorrhages in 7.3 per cent. of typhoid patients, and Griesinger in 5.3 per cent. We have ourselves seen, in the medical clinique at Leipzig, 45 intestinal hæmorrhages in 472 cases, i. e., in 9.5 per cent. In individual epidemics the frequency varies greatly. It rose in 1880 to eighteen per cent.

Intestinal hæmorrhage is always a grave symptom. Even slight hæmorrhages deserve consideration, for they may be the precursors of severer ones. And yet intestinal hæmorrhage, even if profuse, is not necessarily fatal. Of the above forty-five cases of typhoid with hæmorrhage, twenty-six ended in complete recovery. In eight cases, death occurred as the immediate result of the loss of blood. Eleven ended fatally after a time.

After every considerable intestinal hæmorrhage, the symptoms of general anæmia, often even of collapse, appear. The fall of the bodily temperature has been already mentioned. The hæmorrhage has sometimes a favorable influence on severe cerebral symptoms, for consciousness succeeds to the previous stupor or delirium. Often the hæmorrhage is directly followed by recovery from the disease.

Much more ominous than the intestinal hæmorrhage is the occurrence of perforation, as a result of the breaking through of a typhoid ulcer into the abdominal cavity, because, almost without exception, this is followed by a purulent or even ichorous peritonitis. The occurrence of perforation is sometimes marked by a violent pain suddenly felt by the patient; but it may also, even in severe cases, take place insidiously. The abdomen is generally (not always) greatly distended and very tender on pressure, so that even in stupor patients groan while being examined. If gas has entered through the opening into the peritoneal cavity, we often observe absence of the ordinary dullness over the liver; but this symptom is to be employed cautiously as a factor in diagnosis, for absence of hepatic dullness may also result from distended intestines lying in front of the liver. When perforation has occurred, the patient soon looks collapsed, with cheeks fallen in and sharp, cool nose. Frequent eructations and vomiting often follow. The pulse becomes small and very frequent. The temperature generally falls as the peritonitis begins, and later it usually undergoes great variations.

Perforation of the intestine occurs most frequently in the third or fourth week of the disease. In sluggish cases, however, we can not be without apprehensions of it till a late period. The perforation generally takes place in a coil of the lower part of the small intestine, and with marked relative frequency in the right side of the pelvis—seldom in the vermiform appendix or in the colon. With few exceptions, death comes quickly, after a few days at latest. Out of fifty-six fatal typhoid cases in the Leipsic medical clinique we lost five, or nine per cent., from peritonitis following perforation. Here and there a case of recovery has been reported, probably resulting from a limitation of the peritonitis through speedy adhesion of the intestines.

It should be mentioned here that sometimes in typhoid fever a local or general peritonitis may occur through direct extension of the process to the serous membrane without actual perforation. We have seen in one case, as a result of the peritonitic bands and false membranes, complete occlusion of the intestine (ileus), and death.

Swelling of the mesenteric lymph-glands (less often of the retro-peritoneal glands as well) is found in typhoid almost as constantly as the anatomical changes in the intestine. Sometimes they break down, i. e., suppurate. In cases that have passed through the disease we often find considerable deposits of lime in the glands. These changes have a certain clinical importance; for, as already mentioned, we may often venture to refer a more or less tedious recurrent febrile state which has no other demonstrable cause to this lesion of the mesenteric glands. In some rare cases a general peritonitis has been observed as a result of the bursting of a suppurating gland.

The swelling of the spleen (acute splenic tumor) is, in typhoid fever as well as in many other acute infectious diseases, one of the most constant symptoms. The enlargement of the spleen can often be demonstrated as early as the end of the first week, and is therefore of considerable diagnostic importance; but percussion of the spleen is sometimes decidedly difficult and deceptive in this disease because of the existence of tympanites. The surest demonstration of splenic enlargement is therefore always by means of palpation, which, after a little practice, gives a positive result in the majority of cases. Absence of splenic tumor is most frequently observed in elderly typhoid patients. The spleen may also diminish considerably in size after severe intestinal hæmorrhage. Pain in the splenic region, resulting from tearing of the distended capsule, is comparatively rare. The splenic infarctions which sometimes occur may, in exceptional cases, prove the starting-point of a peritonitis.

Hepatic symptoms are seldom seen in typhoid fever, except that there may be a moderate swelling of the organ. The anatomical changes of "parenchymatous degeneration," and the frequent formation in the liver of the small lymphomata which Wagner discovered, have no clinical significance. The bile secreted is generally pale and scanty. This is a partial explanation of the light color of the stools. A very rare complication, which we ourselves observed in one case, is acute yellow atrophy of the liver.

The stomach presents no especial anatomical changes in typhoid. Anorexia is an almost invariable symptom in the beginning and during the course of all severer cases. There is seldom any desire for food till recovery begins; but then, if convalescence is undisturbed, the appetite soon attains an enviable keenness. Vomiting in the beginning or course of the disease is an exception, unless after some error in diet. We have already mentioned it as a symptom of peritonitis.

The changes in the mouth and throat of typhoid patients deserve the careful attention of the physician. The lips and tongue are in severe cases dry and fis-

sured. The lips are often covered with dry, black crusts, sometimes described as a "fuliginous coating." The tongue is apt to be thickly coated at first, but later cleans off from the edges and tip. In severe cases, especially if the mouth is not properly cleansed, a rather severe stomatitis may occur and produce superficial ulceration of the buccal mucous membrane and of the edges of the tongue. The gums sometimes become spongy, and are apt to bleed, as if scorbutic.

Actual sore throat, at least, according to our experience in Leipsic, occurs but seldom at the beginning of typhoid fever. The difficulty in swallowing, often complained of by patients, is generally due to dryness of the pharynx. In certain epidemics, however, the occurrence of sore throat at the beginning of the illness has been frequently observed. It may even happen that this early sore throat is accompanied by an erythema diffused over the body, so that at first suspicions of scarlet fever arise. In rare cases (so-called tonsillo-typhoid or pharyngo-typhoid) there are seen upon the tonsils peculiar whitish elevations, which later ulcerate. These are probably to be regarded as a specific typhoid lesion of the tonsils. It should also be mentioned that in severe cases there is often an extensive growth of thrush in the mouth and throat, and this may spread quite a distance down the oesophagus.

The changes in the mouth and throat are of especial interest, for the reason that they may be directly propagated to important neighboring organs. Starting from the pharyngeal cavity, the pathogenic agent, probably in most cases the staphylococcus, may penetrate through the Eustachian tube into the middle ear. Thus arise those inflammations of the middle ear which are not very rare in severe cases of typhoid, and which lead to perforation of the membrana tympani and to purulent discharges from the ear. The not infrequent inflammation of the parotid gland is also, as we believe, occasioned in a similar way, the inflammatory agent reaching the parotid gland from the mouth by way of Steno's duct. We do not regard the otitis and parotitis as especial localizations of the typhoid poison, but as genuine complications (secondary disease), for the occurrence of which typhoid fever merely furnishes the occasion, as when the mouth is imperfectly cleansed. The parotitis appears most frequently in the third week, and generally on one side, though sometimes on both. It almost always becomes purulent, and discharges either externally or into the external auditory meatus, unless there is a timely incision.

**2. Organs of Respiration.**—Affections of the lungs are among the most frequent and important complications of typhoid fever, but are for the most part not a direct result of the typhoid infection. The bronchitis very often found in severe cases, and especially in patients who do not come till late under proper care, certainly is chiefly dependent on the imperfect expectoration of the bronchial secretions and on the inhalation of inflammatory agents coming from the mouth and throat.

Numerous cases of typhoid of slight or average severity, under proper care, run their course without any considerable bronchitis. In many other cases, and even severe ones, the bronchitis remains within moderate bounds, especially if the patient is brought promptly under proper care and treatment; but in severe cases, where marked disturbances of the nervous system arise, and the patient in his stupor expectorates little, swallows things the wrong way, and lies all the time on his back, passive and collapsed, the occurrence of a severe, diffuse bronchitis, especially in the lower lobes of the lungs, can hardly be avoided. Nor in such cases is there generally a mere bronchitis, but a more or less extensive catarrhal, lobular pneumonia, to be classed therefore under the so-called inhalation pneumonias (cf. chapter on lobular pneumonia). What was formerly termed "hypostatic pneumonia" is also almost invariably to be put in this group.

From the way in which these pulmonary disorders arise, we can understand why the bronchitis sometimes takes on a putrid character, and why the lobular infiltrations are, in severe cases, transformed into genuine gangrene. If such spots touch the pleura, they occasion the development of a pleurisy which is almost always purulent. In rare cases, pneumothorax may arise as a sequel to the perforation of a gangrenous infiltration into the pleural cavity. Various circumstances promote the occurrence of pulmonary symptoms. Thus we find it especially easy for a severe bronchitis and its sequelæ to be developed, in the case of elderly persons, or the kyphoscoliotic, or the corpulent, or patients who have previously suffered from emphysema or cardiac disease.

The subjective thoracic symptoms, in typhoid patients who have pulmonary complications, are generally not very prominent. It is only occasionally that patients complain in the early stages of typhoid fever of pain, and of a sense of oppression in the chest, or of cough, or of a stitch in the side; and even when such symptoms exist, the physical examination may give comparatively insignificant results. The severer pulmonary complications are seen mainly in those whose intelligence is more or less blunted, and who, therefore, make little complaint, are not much disturbed by the dyspnoea, and cough and expectorate little. A careful physical examination alone can enlighten us as to their condition. On auscultation, sibilant rhonchi are the chief signs observed in the milder cases. In the severer ones there are moist, fine, and coarse râles, especially numerous toward the base of the chest. If there are abundant moist râles, we may infer that there is a lobular pneumonia, although this can not be demonstrated with certainty till the separate islets of infiltration unite into a more extensive solidification, so as to afford dullness on percussion.

In addition to the pulmonary lesions already mentioned, genuine croupous or lobar pneumonia does occur in typhoid fever. Probably this must be regarded as a direct result (localization) of the typhoid poison, although this croupous pneumonia is not anatomically distinguishable from the common, genuine pneumonia. It often appears as early as the second week, and attacks the lower as well as the upper lobes. Liebermeister states that he has sometimes observed it during convalescence.

Especial interest attaches to those cases of typhoid fever which begin with a lobar pneumonia. Often there is at first not the slightest suspicion of a typhoid fever, for the disease is regarded as an ordinary croupous pneumonia; but it is usually to be noticed that the illness does not begin suddenly with a rigor, but more gradually, and that from its incipency the constitutional symptoms, the headache and splenic tumor, are more prominent than is usually the case in pneumonia. At the end of the first week's illness there is no crisis, but persistent fever. Now the pulmonary symptoms often retreat more and more to the background, while, on the contrary, diarrhoea and rose-spots appear. The spleen is enlarged. In short, the clinical picture of typhoid is developed. It is not unnatural to suppose, although there is yet no absolute proof of the fact, that in these cases, which are fittingly termed "pneumo-typhoid," the infection with the typhoid bacilli has taken place exceptionally in the pulmonary area, and that, therefore, the first pathological changes are developed in the lungs.

*Laryngeal Lesions.*—The same causes which produce the bronchitis result also in a simple catarrhal laryngitis, with hoarseness. This is in severe cases accompanied by superficial ulcers on the vocal cords or the posterior wall of the larynx. Sometimes, again, the lesion is due to mechanical causes, constituting the so-called "*decubitus laryngis*." The disorders which attack the less superficial structures of the larynx are fortunately rare. Chief among them is a laryngeal perichondritis of the arytenoid cartilages. This complication is justly regarded as of bad

omen, and may lead to the rapid development of œdema of the glottis, with great laryngeal obstruction and threatening suffocation. These severe laryngeal affections in typhoid are regarded by some authorities, especially by Klebs, as always the direct effect of the infecting poison; but in most cases they are probably due to an invasion of staphylococci or some similar microbes. We have several times seen laryngeal croup in typhoid fever, and it is a very dangerous symptom. We are inclined, however, to the belief that it was in every case a secondary disease.

Among symptoms referable to the mucous membrane of the nose, epistaxis is important. It occurs in the beginning of typhoid with tolerable frequency, and is in one way not unfavorable, for it often mitigates the patient's headache. At a later period nose-bleed may become a very unpleasant complication, as it is sometimes very difficult to check. We have even seen one fatal case due to persistent nose-bleed. Other nasal symptoms are exceptional. There is an old saying that typhoid never begins with a coryza.

**3. Nervous System.**—The old term "nervous fever," which is still used by the laity, shows how frequent and severe are the nervous derangements which occur in typhoid. In cases of any severity there is almost always a certain dullness of intellect, often amounting to apathy and somnolence. The patients give monosyllabic and incomplete answers to all questions, and their statements about their previous history are often disordered and contradictory. There may even be sopor or a deep coma in the worst cases. All cases of this sort in which there was a condition of intellectual enfeeblement were termed by the old physicians "*febris nervosa stupida*," in contrast to the "*febris nervosa versatilis*," that form in which abnormal mental activity or delirium predominates. In severe cases delirium is very frequent. It is generally worse at night, and at times when the patient happens to be left alone. Very often he tries to leave his bed, because of his delusions, and talks of persons and things with which he was formerly familiar; or he is very noisy and restless, sometimes shrieking from groundless fears. We may add that these diverse nervous symptoms frequently succeed one another, or appear in combination. Sometimes a soporose patient may be heard softly whispering to himself in "muttering delirium."

Certain motor disturbances are often combined with considerable impairment of consciousness. There is a slight twitching of the muscles of the face and extremities. The old authorities gave the name *subsultus tendinum* to the sudden leaping into prominence of the sinews thus caused. It is best seen on the back of the hands. In severe cases the patient is sometimes observed to grind the teeth together; this is due to a cramp-like condition of the muscles of mastication, and is justly regarded as ominous. We often see persistent tremor of the extremities and lower jaw; and it is especially in these cases, as we have demonstrated upon numerous patients, that the tendon reflexes and the mechanical excitability of the muscles are much increased. If deep coma comes on, the muscles become lax, the motions of the eye are not co-ordinated, and reflex excitability diminishes, or is wholly extinguished.

Headache is one of the most constant symptoms in the beginning of the disease. It is usually referred to the forehead or temples. The pain may be very violent, and sometimes takes on almost a neuralgic character. It almost always subsides in the second week.

If we seek the cause of these nervous symptoms, which are often so severe, we find that the anatomical changes in the nervous system, including the brain, bear no relation whatever to the severity of the symptoms observed during life. We sometimes meet with minute hæmorrhages in the cerebral meninges, or meningeal opacity or œdema, or a moist condition of the cerebral parenchyma; but the connection of these and similar changes with the symptoms of the disease is often

more than doubtful. Nor can the microscopic alterations in the brain, which have been reported, be regarded as important and authoritative. It is only in very rare cases that large cerebral hæmorrhages or purulent meningitis have been found. As to this last, we should always be very cautious in making a diagnosis, as symptoms which would seem to be most conclusively meningeal—such as stiffness of the neck, rigidity of the whole spinal column, and occipital headache—may appear in typhoid patients, and yet the autopsy show no trace of meningitis.

One theory, which has Liebermeister for its chief supporter, and which has won a tolerably wide-spread acceptance among physicians, is that the nervous symptoms are chiefly a direct result of the febrile temperature. It is impossible, however, for us to regard this view as universally true. The unprejudiced consideration of a large number of personal observations prevents it. Although it is undeniable that elevated temperature has a harmful influence on the nervous system, yet in numerous cases there is no relation between the height of the fever and the severity of the nervous derangements. There are cases in which the fever remains continuously high for days, while the patient feels perfectly comfortable and presents no symptoms of any important cerebral disturbance. The opposite class of cases is still more numerous, in which from the very start there is always a low temperature, and, notwithstanding, the most severe nervous symptoms arise. Fräntzel has published very striking cases of this sort.

Hence we must seek for some other special cause of the severe nervous symptoms, and according to our present views this cause must be the intoxication resulting from the specific infection. We know that all bacteria produce, by their own tissue-metamorphosis and the chemical processes which they excite in their neighborhood, certain chemical matters which, especially in the case of the so-called "pathogenic bacteria," seem to be similar to the alkaloids ("ptomaines" and "toxines"), and exercise a decided poisonous influence upon the body, and especially upon the nervous system. These products are formed by the typhoid bacilli, enter the blood, and are the chief cause of the nervous phenomena. The difference in the violence of the latter in different cases probably depends mainly on a difference in the amount, and perhaps also in the quality, of the toxins produced by the typhoid bacilli, and probably also in the different susceptibility of individuals to the poison. The reason that the influence of these poisons is not much greater than it is, is that they are in part destroyed within the body and in part excreted with great rapidity, the channel of exit being mainly the kidneys. Thus is explained the interesting fact discovered by Lépine, Bouchard, and others, that the urine of typhoid patients possesses poisonous properties not present in normal urine.

That the appearance of the nervous symptoms is dependent not only on the material causes, but also on the susceptibility of the individual, is shown by the fact that certain patients are especially prone to exhibit marked nervous phenomena; for example, hard drinkers, "nervous" individuals, and also those who have suffered violent emotional disturbances shortly before the onset of the disease.

Actual insanity is not very infrequent during the course of typhoid, or in convalescence. It generally takes the form of melancholia. We have repeatedly seen patients in such a state that they would lie almost motionless in bed, with eyes open, and perhaps assert that they were dead! In other cases there is mental excitement, sometimes combined with hallucinations, or there is confusion of ideas. In one case, in a girl who was evidently predisposed to nervous disorders, we saw typical hysterical insanity break out during the fever. Sometimes the mental excitement at the beginning of a relapse terminates in actual insanity.

Few of the psychoses which arise during or at the end of typhoid outlast convalescence.

We have still to mention a number of nervous diseases that develop in the course of typhoid or after its decline. Neuralgia is sometimes seen, as well at the beginning as at the end of the disease. It is most frequent in the regions supplied by the trigeminus and the occipital nerves. Great hyperæsthesia of the skin and muscles is not rare during convalescence. It attacks the lower extremities by preference. Paralysis of single muscles (e. g., of the serratus magnus), or paralysis of a single extremity, has been repeatedly observed as a sequela. The paralysis is generally of the atrophic variety, and is probably, as a rule, due to neuritis. Ataxia and spastic paralysis of the lower extremities are rare sequelæ. Finally, there are sometimes developed, either in the course or at the conclusion of typhoid fever, the symptoms of a localized cerebral disorder (e. g., hemiplegia and aphasia), the anatomical cause of which varies. There may be a hæmorrhage or an embolism, and probably in still other cases a localized encephalitis.

**4. Circulatory System.**—Disturbances of the heart such as to produce striking anatomical changes are very rare. Endocarditis and pericarditis are, however, possible. The slight mitral endocarditis sometimes found at the autopsy has no clinical significance. On the other hand, great weight is laid by some authors upon the parenchymatous or fatty degeneration of the heart. They say it is often the cause of cardiac failure. We can not admit this, for experience shows that the two do not stand in any constant relation to each other.

The pulse is almost always rapid, although often not so much so as the height of the temperature might lead one to expect. It averages from 90 to 110, and often more. When it keeps at 140 or higher, in adults, it is always an unfavorable symptom. This abnormal frequency is often in part due to the high temperature; but there are other factors. Temperature and pulse do not correspond in all cases. Sometimes the pulse will have a normal or even subnormal frequency throughout the entire attack, despite the fever. Temporary accelerations are easily produced by mental excitement or bodily exertion, as by sitting up in bed. In convalescence the rate is frequently subnormal.

Slight irregularities of the pulse are not rare, either in the acme or the decline of typhoid. Marked irregularity is always a grave symptom, although in many cases it passes off and the patient recovers.

Microtism is so frequent that many elderly physicians still regard it as characteristic of the disease. It is often, however, equally marked in other acute diseases. Its cause is diminished arterial tension.

The diminished cardiac activity may result in venous thrombosis, especially in the lower extremities. This sometimes causes swelling of one of the lower extremities during convalescence. The swollen member generally regains its normal size after some weeks. In other cases the thrombosis occurs earlier, and in patients who are still too vigorous to suffer from cardiac weakness, so that we are forced to the conclusion that there is some local specific cause. A possible, but fortunately infrequent, result of these thrombi in the lower limbs is pulmonary embolism and sudden death.

In severe cases, which end in death, cardiac thrombi are sometimes found, with emboli in the lungs, spleen, kidneys, or other organs.

Oedema of the ankles and legs is very often seen in convalescents, especially when they first get out of bed. It is due to the weakness of the heart and changes in the vascular walls. Once we saw a general dropsy develop at the end of a severe attack in a girl of fourteen. The autopsy disclosed no other possible cause for it than the extreme atrophy and flabbiness of the heart.

**5. Skin.**—The eruption seen in typhoid fever is characteristic. The rose-spots

appear at the beginning of the second week, usually on the trunk, and chiefly on the abdomen. The number varies greatly. Rarely they are entirely absent, most often in elderly persons. Sometimes they are very abundant, and extend to the thighs, the arms, and even to the neck and face. Often they vanish after a few days, but they may persist much longer. In the latter case they may become to a very slight degree petechial, so that they will not entirely disappear on pressure. They often occur in successive crops. We have even seen several cases where new rose-spots kept coming for some days after the fever had disappeared.

As to other cutaneous eruptions, we may mention first of all that herpes labialis is so rare in typhoid that in cases of doubtful diagnosis it is a factor in excluding that disease. Miliaria, urticaria, and superficial pustules are sometimes observed. Occasionally little bluish spots appear, especially on the trunk. These used to be called "*taches bleuâtres*" (pelioma typhosum); but later observations show that they are not connected with typhoid fever particularly. They are due to pediculi. We might use the term pelioma typhosum to designate the kind of vesicles which we have repeatedly seen on the abdomen in severe cases. They are about the size of peas, and have sero-hæmorrhagic contents. Boils and superficial abscesses are frequent, especially as disagreeable sequelæ in convalescence from severe cases. There are often abscesses of the sweat-glands in the skin of the axilla during convalescence. All these and similar cases of suppuration in typhoid fever do not depend upon the original cause of the disease, but upon secondary pathogenic germs, such as the staphylococcus or streptococcus, for whose entrance the typhoid process has merely prepared the way. Extensive ecchymoses are very rare, and are symptomatic of a general hæmorrhagic diathesis. Petechiæ are frequent during recovery. They are generally seen in the follicles of the skin below the knee. There have been a few cases of gangrene in the lower extremities, especially in the toes. We saw in one patient an extensive gangrene of the skin of the abdomen. Its cause could not be determined.

Finally, we must mention that bed-sores are prone to develop in severe or neglected cases. The localities most often attacked are the nates, the furrow between them, and the heels. A bed-sore may be so extensive, and accompanied by such undermining of the skin, as to be a dangerous or even fatal complication.

The epidermis often scales off to a considerable extent during convalescence after a severe attack of typhoid. Everybody knows how the hair falls out after the fever, but it is sure to grow again. The nails also are not infrequently affected, becoming rough and brittle, or even falling off.

**6. Muscles, Bones, Joints.**—Zenker has discovered a degeneration of the voluntary muscles which occurs in typhoid as well as in other severe diseases. It is called the "granular" or "waxy" degeneration. Whether it has clinical symptoms can not be determined. Perhaps it may explain the great muscular hyperæsthesia which is often observed, and the muscular pains, which may be very trying. Severe cases sometimes have hæmorrhages into the muscles, particularly the rectus abdominis.

Lesions of the bones and joints occur but seldom. We have seen periostitis of the tibia, and of a rib, during convalescence. Swelling of the joints is equally rare. If there is a purulent arthritis, it is always due to some secondary infection (*vide supra*).

**7. Genito-urinary Apparatus.**—Genuine, acute, hæmorrhagic nephritis is a very rare complication. It does occur, however, and has even given rise to the establishment of a special "renal form of typhoid fever" (nephro-typhoid). This name applies especially to those cases in which a severe acute nephritis is the predominant symptom at the start, while at a later period the course of the fever, the intestinal symptoms, the rose-spots, etc., show the disease to be typhoid fever.

Nephro-typhoid is analogous to pneumo-typhoid and tonsillo-typhoid. A simple so-called febrile albuminuria occurs very frequently at the acme of typhoid, and is not to be interpreted unfavorably. It is probably the result of that slight parenchymatous degeneration of the kidneys which occurs in typhoid with the same frequency as in most of the other severe infectious diseases. There does not seem to be a direct relation between the albuminuria and the fever, although some authors assume it to exist. It is more likely that the renal epithelium is injured by the noxious products which have been formed in the body and excreted by the kidneys. In other respects the urine presents the same peculiarities as in most other severe febrile diseases: its amount is diminished; its color dark; its specific gravity increased; the excretion of urea greater than normal. It should be added that the urine at the height of the disease presents Ehrlich's "diazo-reaction" in almost all cases.\* Cystitis is not a rare development toward the end of the illness. It is probably always secondary.

In men, orchitis is sometimes observed. Women often have their catamenia at the beginning of typhoid. Later in the course of the disease, and in convalescence from severe attacks, the menses are often absent for several periods. In pregnant women there is considerable danger of abortion or miscarriage.

#### PECULIARITIES IN THE COURSE OF THE DISEASE.

The above statements show an almost inexhaustible variety in the possible complications of typhoid. The course of the disease as a whole may likewise present many diverse forms and peculiarities. We shall attempt merely to cite the most essential.

The numerous light and rudimentary attacks (*typhus levissimus*) are first to be mentioned. It was not recognized till lately that they belonged to typhoid fever at all (Griesinger). They used to have all sorts of names applied to them, the favorite term being "gastric fever." This light form lasts eight to fourteen days. The fever is moderate and often decidedly remittent. There is almost no proper fastigium. The typhoid symptoms are but slightly developed. There are no severe pulmonary or cerebral symptoms. There is generally a moderate diarrhoea, the spleen is plainly enlarged, and often rose-spots can be found. The diagnosis of these cases is of course difficult in proportion to the scanty development of typhoid symptoms. It is best established by demonstrating an ætiological relation between these cases and others which are plainly typhoid fever.

Abortive typhoid is justly distinguished by Liebermeister from *typhus levis*. The name belongs to cases which begin with severe symptoms and high fever, as if they were going to be grave, but in which these violent symptoms disappear after a few days and give place to a rapid convalescence.

On the other hand, there are cases which for a long time cause so little subjective discomfort that the patient does not even go to bed (walking typhoid). It is not till quite late that there occurs a sudden change for the worse, or some severe complication. Thus it has happened that people who were apparently healthy

---

\* This reaction consists in the red coloration of the urine upon the addition of Ehrlich's reagent (chiefly sulphanilic acid) and ammonia. For particulars, see treatises upon chemical analysis. [Ehrlich's test is carried out as follows: Solution 1 consists of strong hydrochloric acid, one part, mixed with twenty parts of a saturated aqueous solution of sulphanilic acid. Solution 2 is a one-half-per-cent. solution of sodic nitrite in water.

A test-tube is one-eighth part filled with solution 1, and five to ten drops of solution 2 are added to this; a quarter of the test-tube of urine is then added, and, lastly, enough ammonia to make it strongly alkaline. The deep-red color, which appears promptly, is not so characteristic as a green precipitate of phosphates, which appears at the bottom of the tube after standing for twenty-four hours.]

have suddenly had all the symptoms of a severe peritonitis due to perforation and have died, the autopsy disclosing the lesions of the third week of typhoid fever.

The individual circumstances are very important in weighing each case, for they may modify the disease in many ways.

In children it is a remarkable fact that typhoid ulcers are much less frequent than in adults. This explains why intestinal hæmorrhage and peritonitis are much rarer in children. Severe cerebral symptoms are, on the other hand, very frequent. In severe cases children sometimes exhibit the peculiar symptom of a continuous penetrating screaming. In other, mild, cases the children are soporose.

In the aged the diagnosis of typhoid is often very difficult, since the course of the disease is frequently irregular. Generally the fever is not very high, and it very seldom exhibits distinctly the type described above. The pulmonary or cerebral symptoms predominate as a rule.

In the corpulent, typhoid fever is often very severe, so that our prognosis must always be rather grave, especially if pulmonary symptoms arise.

Hard drinkers are also in especial peril in this as in all other acute diseases. Dangerous cardiac weakness is prone to appear. Severe cerebral symptoms are frequent. It is, however, surprising that true delirium tremens is relatively infrequent, although so common in pneumonia.

The influence of previous strong mental excitement and of certain already existing diseases (cardiac disease, emphysema, kyphoskoliosis, etc.) has been already mentioned. Finally, we repeat that often the different epidemics present certain peculiarities. For instance, in one the type of the disease will be severe, in another mild. In one epidemic relapses are comparatively frequent, in another exceptional. The same is true with regard to the frequency of the appearance of certain symptoms, such as intestinal hæmorrhage, pneumonia, or nephritis. Indeed, it has even been observed that those cases which occur during a given epidemic in the same family or house or block sometimes present striking resemblances to one another ("group typhoid" of E. Wagner and others).

#### RELAPSES OF TYPHOID FEVER.

Typhoid fever exhibits in many cases the peculiarity of repeating itself completely after having run its entire course and disappeared. This process is called a relapse. It is in all probability the result, not of a fresh infection of the system from without, but of a renewed development, or possibly of a second generation, of the infectious germs already present. A typical relapse is like a first attack in all clinical and anatomical particulars, with this difference, that everything is more condensed, and lasts a shorter time than in the first attack. The interval between the two, during which there is no fever, lasts seven to ten days. It may be longer, and is often shorter. Sometimes the relapse follows immediately upon recovery. Indeed, it may even happen that, before the patient has completely recovered, his temperature begins to rise again in the characteristic step-like way. To such cases as this last the term *recrudescence* is applied. Except in the time of its beginning, it may be just the same as a genuine relapse. In the interval between the two attacks many persons are perfectly comfortable, and appear to be fully convalescent. There is often, however, a slight evening rise of temperature. It is noticeable that the splenic tumor does not completely disappear after the first attack in many cases which are followed by a relapse.

The relapse is generally briefer, as we have said, than the first attack, seldom lasting more than fifteen to eighteen days. The temperature rises more rapidly, perhaps in two or three days. The fastigium is shorter, the decline more abrupt.

The absolute height of the temperature may be very considerable, even exceeding that in the first attack. Rose-spots appear as soon as the third or fourth day. The stools become liquid, the spleen enlarges again, and all sorts of complications may arise. The danger occasioned by a relapse may, however, be overestimated. On the whole, a relapse is not so very dangerous, and it is especially noticeable that the subjective symptoms, such as headache, are often slight. A severe relapse may follow a mild case. In other instances the relapse may prove merely rudimentary.

The frequency of relapses varies considerably in different epidemics. In Leipzig, we had relapses in about nine per cent. of all cases, but in separate years the percentage varied between four and sixteen. Out of about five hundred cases we have seen three in which there were two successive and typical relapses.

**Diagnosis.**—The diagnosis of typhoid fever may be perfectly easy, but, if the case be anomalous, or come under observation at a late period, it may be extremely obscure. Inasmuch as a search for the specific bacilli is too difficult and troublesome, for the practicing physician, the diagnosis of the disease must be made from its course and symptoms. Important factors are the gradual onset, then the height and course of the fever, with no demonstrable localized disease, and the rose-spots. Less characteristic, but still of value, are the stools, the tympanites, and the swelling of the spleen. *Ætiological* factors, such as the occurrence of undoubted cases of typhoid in the neighborhood, are of great diagnostic value in obscure cases. Sometimes the diagnosis can not be established till the appearance of certain symptoms, like intestinal hæmorrhage, a characteristic mode of convalescence—viz., by lysis—or a relapse. It is an important rule not to make a diagnosis of typhoid after a single examination. It is generally necessary to observe the case accurately for several days before the diagnosis can be established. The differential diagnosis from other acute diseases, such as miliary tuberculosis, acute endocarditis, meningitis, etc., will be considered in discussing these diseases.

**Prognosis.**—A perfectly favorable prognosis should never be made. Cases which seem the mildest may become dangerous. Yet, if there are good nursing and good treatment, typhoid fever is not a particularly dangerous disease, and we may hope for recovery even in very severe attacks. The danger lies, first, in the severity of the infection, as shown chiefly (though not wholly) by the height of the fever and the intensity of the general symptoms. A further danger is the appearance of the complications already enumerated and discussed. Thirdly, the constitution and condition of the individual are important. The circumstances coming under this head have likewise been repeatedly mentioned above. All these factors must be carefully estimated before we decide as to the danger in each case and make our prognosis.

The mortality in typhoid varies greatly in the separate epidemics. The severe cases are undoubtedly more frequent at some times than at others. This renders it difficult to give statistics which are universally applicable. We may in general reckon on an average mortality of about ten per cent., and measure the severity of separate epidemics by this standard. Numerous observers agree that the treatment now in vogue has decidedly diminished the mortality. It was formerly not rare for it to reach twenty or twenty-five per cent.

**Treatment.**—A specific cure for typhoid—i. e., some remedy to destroy the specific cause of the disease within the system, or to render it harmless—is as yet unknown. Antiseptic and antizymotic drugs, such as quinine and antipyrine (*vide infra*), do have a certain influence upon the fever, but they are not capable of essentially modifying the course of the disease as a whole, at least not in such doses as we dare administer. The continued internal use of car-

bolic acid (grains five to ten, gramme 0·30-0·50, or more, in the course of twenty-four hours) is the means chiefly recommended lately for this purpose; but we doubt if it is of much benefit. Liebermeister ascribes to iodine a demonstrable, although slight, beneficial influence. Other physicians had previously recommended it. Four to five drops of the following solution are given every two hours in a wineglass of water: Iodine, one part; iodide of potassium, two parts; distilled water, ten parts. We have had no personal experience with this remedy.

Calomel is also said to have a specific effect on typhoid. Wunderlich and others have noticed that if a few rather large doses of calomel be given at the beginning of the disease, it will on the average run a lighter and more favorable course than otherwise would have been the case. Wunderlich believed that typhoid fever may sometimes be aborted by this method. Although we can hardly expect this, it is really an efficient means of procedure, which we have often found satisfactory, to give two or three powders, of five grains (0·30 gramme) each, of calomel, as the first prescription, to patients who come under treatment in the first week or the beginning of the second. As there is generally constipation, the laxative effect is also beneficial. Moreover, it often lowers the temperature somewhat. A moderate diarrhoea is not a contra-indication, but, if the bowels be very loose, the calomel should be omitted.

Ergotine may be mentioned as another drug which is said to act specifically. It has been lately used, chiefly by French physicians, in doses of twenty to forty-five grains (1·50-3 grammes) in twenty-four hours. Again, subnitrate of bismuth is used (by the French to the amount of four to eight drachms—grammes 15-30 *pro die*), and naphthaline in single doses of three to eight grains (0·1-0·5) or in the course of the day seventy-five grains (5·0). We doubt if these remedies will be popular long.

In the present state of our knowledge the treatment of typhoid must still be chiefly general and symptomatic, and in one sense prophylactic. We must fight the symptoms already present, and further seek, as far as possible, to defend the patient from the attack of certain dangerous secondary disorders. Starting out with this view, the proper treatment of typhoid fever is a task of the highest importance, and by no means a thankless one.

We will begin by considering the general treatment. The sick-room must not be too warm, and must be frequently and thoroughly aired. The sick-bed must be well cared for. If pains be taken to prevent bed-sores, we shall obviate one source of pain and danger (*vide supra*), and save ourselves and the nurse much trouble. Those who are very sick should therefore be laid on an air-cushion, or, if possible, a water-bed. The patient should be told not to lie always upon his back, but to change now and then upon his side. The back, the region of the sacrum, and the heels are to be often bathed with spirits of camphor or brandy. The minutest bed-sore is to be treated carefully. It should be cleansed twice a day (rinsed off with a weak solution of salicylic or carbolic acid), and done up with an ointment containing Peruvian balsam, 1-30.\* If the bed-sore be extensive, dusting with iodoform is very efficient treatment. We should be particularly careful not to let the skin be undermined. If this has already occurred, we must be prompt in the use of the knife or drainage-tube.

We can not recommend too strongly that the mouth should be kept clean. In a light case the patient can see to this himself, but otherwise the mouth and tongue must be frequently cleansed with a linen cloth wet in cold water or a solu-

\* The unguentum balsami peruviani is made by mixing one part of balsam very exactly with thirty parts of the glycerite of starch (B. P.). It is not official in Germany.—TRANS.

tion of borax (1 to 30). Perhaps we need hardly repeat the reason for this excessive cleanliness. It lies in the causative relation between stomatitis and inflammation of the parotid gland, and of the middle ear. If the tongue and lips be dry, they may be touched with glycerine.

The diet must be at once liquid and nourishing. Milk is excellent, and should always be ordered, but will, unfortunately, be taken by very few patients continuously. It is often better borne if coffee or a little brandy be added to it. Cocoa made with milk may also be given for a change. In severe cases Nestlé's food (Kindermehl) has been often employed by us with benefit. Broth and soup, thickened with sago or rice, are also good. They may be made more nourishing by adding an egg to them. If the patient is very anxious to have more solid food, as often happens, we need not hesitate to give him a roll or rusk (Zwieback) that has been softened by soaking. If a patient becomes exceedingly enfeebled we should give him fine shavings of raw beef, regardless of the fever. A little dilute hydrochloric acid might be given with the meat. Beef-tea would be still better than the raw meat, and is to be strongly recommended. The various preparations of meat which are now made (meat-solution, meat-peptones, etc.) may be sometimes useful. Where the fever takes a sluggish course, we must often begin to give stronger nourishment before the fever has ended. The best drink is cold water, which the patient would often not think of using unless we offered it to him. Lemonade and similar preparations generally become distasteful in time. Drinks containing carbonic dioxide are to be avoided, because they increase the meteorism. Cold tea with milk is good. In severer cases we should give some good strong wine, such as port, Malaga, or Hungarian wine. If the patient desires beer, we need not hesitate to give it in moderate amount. During convalescence we should be very careful about diet, since errors often have disagreeable consequences. We must wait till there has been no fever at all for seven to ten days before we allow a solid, animal diet, and return by degrees to common sorts of food.

The general and dietetic treatment which we have thus far discussed is very important. Outside of this, it is our opinion that there is only one method of treatment to be chiefly considered—at least under the present limitations of our therapeutic ability. This method consists in the persistent use of cool baths, as first practiced by Brand in Stettin. We do not indeed believe that the indications for this method of treatment are exactly what its original promoter held them to be, and we think some of the minutiae of the treatment should be changed. Yet there is at present no other single method of treating typhoid fever which has so numerous and evident advantages for the patient. To carry it out in private practice may often be more difficult than in a well-appointed hospital. However, even in private houses it will generally be possible to manage it, and we regard it as the duty of every physician who undertakes to treat a severe case of typhoid to try his best to have the baths employed.

The great advantages of the treatment by baths are: 1. The baths diminish the fever, if their temperature be only sufficiently low, by direct absorption of heat. The baths thus obviate, as far as possible, all the bad effects which might result from a rise of temperature. 2. The direct influence of the baths upon the nervous system is still more important. The intellect becomes clearer, the apathy and dullness diminish. In fact, if baths be used, we do not see nearly so often as formerly the grave "typhoid condition." It is thus evident that bathing not only causes an improvement in the subjective sensations of the patient, but brings in its train many other beneficial effects. The patient takes his nourishment better, does not so often swallow the wrong way, coughs more effectively, is easier to move, and his body and his mouth can be better cleansed. 3. The influence of

the baths upon the respiratory organs is of the greatest importance. We refer especially to the stimulation to deeper inspirations, and the promotion of expectoration. The best proof of the benefit of this influence is the circumstance that, if patients are subjected to baths from the start, it is comparatively a rare thing for severe bronchitis, atelectasis, and catarrhal pneumonia to develop. 4. The good care of the skin, which the bathing makes possible, is not to be despised. Since this treatment has been introduced, bed-sores are much rarer in typhoid than before. 5. Lastly, the baths are sometimes observed to have a diuretic effect.

What has been said shows that the height of the fever is by no means the sole indication for the employment of baths, at least in our opinion. The condition of the nervous system and of the respiratory organs is also to be considered. It is true that numerous mild cases run a favorable course without a single bath; but we should always remember that this treatment is not only directed against the symptoms already existing, but has also a prophylactic importance, since it tends to prevent any severe cerebral or pulmonary manifestations.

We will pass on to the special method of carrying out balneo-therapeutics in typhoid. Full baths are generally employed, immersing the patient to his neck. The tub must stand, if possible, by the bedside. In hospitals, where there are beds on rollers, it is a better way to wheel the patients into the bathroom. All who are severely ill should be lifted into the bath and there held and supported, to avoid any bodily fatigue. During the bath the skin should be gently rubbed. This averts unpleasant sensations of chilliness. The temperature of the water should not be set too low, especially for the first baths. We begin at 85° to 90° (24° to 26° R.), or, if the individual be elderly or sensitive, and timid, at even warmer temperatures. When the patient has become accustomed to the temperature of the water, we can cool off the bath still further. Baths below 73° (18° to 20° R.) have scarcely ever been used by us, and we believe that they are seldom needed. A very satisfactory average temperature is 80° to 85° (20° to 24° R.). A bath lasts on the average ten minutes. If the patient feels very cold or very uneasy in the bath, it must be cut short. After the bath the patient is at once lifted into bed, wrapped up in a sheet previously made ready, and wiped dry, with rather vigorous rubbing of the extremities and back. The moist sheet is then removed. The patient is covered up rather warmly, and is given some hot broth or a sip of good strong wine. The effect of the bath upon the temperature is measured about half an hour later by the rectum. If the temperature be 2° to 3° (1° to 2° C.) lower than before, the result is deemed satisfactory. Often the difference is greater, but in severe cases the fever may be so obstinate that the temperature remits only a small fraction of a degree. In such cases it is sometimes permissible to lower the temperature of the bath still more, or continue it a little longer. If cool baths are ill-borne, protracted baths of lukewarm water are sometimes very efficient (Riess, and others).

In so far as the height of the fever furnishes an indication for baths, we may accept, say 103·6° (39·8° C.) in the rectum, as the temperature calling for a bath. As a rule, baths should not be given oftener than every three hours, as otherwise they exhaust the patient. In many cases three or four baths a day are enough. At night we have given baths very seldom, when forced to by extremely high temperatures or other bad symptoms. It must be a mistake to wake a patient who is quietly sleeping, and put him into cold water, even if his temperature is above 104° (40° C.). Likewise, in cases where the temperature shows considerable spontaneous remissions, there may be no use in inflicting a cold bath upon a patient who has high fever only temporarily. On the other hand, even if the temperature be not excessive, or even if it be normal, there is, as we have said, no

better remedy than the baths for severe pulmonary or cerebral symptoms. In such cases we often raise the temperature of the baths a little, and during them we have colder water poured upon the head and back. If we do this, the ears must be stopped with cotton-wool, lest the cold water find its way into them.

It is not always advisable to use baths, however advantageous this treatment may be, in typhoid fever. There are a number of contra-indications which can not be disregarded. First, the occurrence of intestinal hæmorrhage, however slight, and likewise the suspicion that peritonitis is developing, prohibit bathing. In these cases quiet is the very first requirement of the patient, and the baths must be at once discontinued. Further contra-indications are great weakness or great sensitiveness, such that the excitement caused by the bath might do harm. Sometimes baths are followed by severe rheumatic ("rheumatoid") pains in the limbs, and often they seem to promote the occurrence of furunculosis. In such cases it is often necessary to omit the baths, or at any rate to employ them less often and at a warmer temperature. The same is true if a severe laryngeal affection develops, or otitis or nephritis. Nothing seems to us a greater mistake than to attempt to establish a scheme for the treatment of typhoid by baths that shall be always applicable. Here, if anywhere, the only correct way is to treat each individual case according to its special symptoms and circumstances.

We shall now pass on to the consideration of the further symptomatic treatment of typhoid. The first question is whether the fever—that is, the elevation of bodily temperature, as such—demands special consideration. In general, we are of the opinion that the internal antipyretics are seldom indispensable. It is true that by giving quinine (single doses of fifteen to twenty grains, gramme 1 to 1.50) or salicylate of soda (in amounts of a drachm or a drachm and a half, grammes 4 to 6), the elevated temperature may often be considerably diminished; but whether the patient is thereby benefited is at least doubtful. Certainly the unpleasant accessory symptoms caused by the drugs mentioned—viz., vomiting, ringing in the ears, vertigo, and profuse perspiration—make the patient feel decidedly more uncomfortable than he was before. There is also some danger that these medicines may have an unfavorable influence upon the cardiac activity. Decidedly better than quinine and salicylic acid is antipyrine. This substance was synthetically produced by L. Knorr from phenylhydrazin and acetacetic ether, and was first recommended by Filehne. In the dose of fifteen to thirty grains (grammes 1 to 2) it is a very efficient antipyretic. It may be given in wafers or dissolved in water, and it is easy to take. Exceptionally there are disagreeable results, such as vomiting, an eruption resembling measles, or a rigor followed by a return of fever. In severe cases the dose must be repeated after two or three hours. More than eighty or ninety grains (grammes 5 to 6) as a maximum should not be given in one day. The general condition often improves under the influence of antipyrine. Especially is this true with regard to headache, restlessness, and other nervous symptoms. Another very efficient antipyretic is acetanilide, which was lately discovered by Cahn and Hepp, and has already been largely introduced into medicine under the name of antifebrin. One advantage is that it is far cheaper than antipyrine. It is given in doses of four to eight or even fifteen grains (gramme 0.25, 0.5, 1.0) either in wafers or in wine. It usually causes a decided lowering of the temperature, and seldom with any unpleasant effect, such as a chill. One disadvantage, however, is the frequent appearance of a peculiar bluish discoloration of the skin, which is probably dependent upon a change in the coloring matter of the blood, similar to that seen in poisoning from aniline. It is therefore probable that caution should be used in giving the drug. Numerous other antipyretics, such as kairin and thallin, have been proposed, but have not become popular. It is also improbable that a continued administration of

small doses of thallin (two thirds to one grain, gramme 0·04, 0·06) every hour would have a favorable influence upon the course of the disease, although this has been asserted. The newest antipyretic of all is phenacetine, which was recommended by Kast and Hinsberg. Its dose is about fifteen grains (gramme 1).

After all, it should be borne in mind that the only benefit from the internal antipyretics consists in the lowering of the temperature, while baths not only abate the fever, but possess numerous other advantages, as has been already shown. If we had to choose whether to treat typhoid fever exclusively with baths or with antipyrine, and the like, we should certainly choose the baths. We do not by any means desire to banish the use of internal antipyretics from the treatment of typhoid, but only to make their employment more limited than has often been the case. We consider that they are actually indicated only where the fever is high and the employment of baths is for some reason impossible or contra-indicated, or where the fever remains continuously high, despite bathing. In such cases it is often advantageous to combine the bath-treatment and the internal antipyretics, especially in the evening. If patients with a moderately high fever are made to take large doses of quinine and the like, without any satisfactory reason for it, we regard such treatment as at any rate useless and often really injudicious. This is, unfortunately, a common practice, and frequently its only permanent result is a disordered stomach.

[Water or an acid drink should be given frequently by the nurse without waiting for the patient to ask for it, unless the mind is unusually clear. Phenacetine seems to have proved itself less depressing to the heart than its predecessors. The antipyretic dose usual in this country is five grains. A strong protest should be entered against the routine or frequent use of any of these internal antipyretics. If the temperature seems, in itself, to cause restlessness and discomfort, an occasional dose may be given. When used early in the course of the disease, antipyretics may seriously embarrass the diagnosis in doubtful cases. The method of Brand has been slowly working its way in America of late years, and perhaps would have spread more widely and rapidly were it not that we have long been in the habit of frequently sponging our typhoid patients with alcohol and water.]

Another important symptom which needs special treatment is intestinal hæmorrhage. It has been already mentioned that if this occurs, the baths should cease at once. Further than this, the chief remedies are ice and opium. Flat ice-bags are laid upon the abdomen. They should not be too heavy, and should, if possible, be suspended from a hoop. Internally, the patient is given every two hours a powder of one-half grain or one grain (gramme 0·03 to 0·05) of opium, either pure or combined with acetate of lead (opii, gr. ss., grm. 0·03; plumbi acetatis, gr. j, grm. 0·05; sacchari albi, gr. j, grm. 0·05). The object of the opium is to check peristalsis, and thus promote the formation of a clot in the bleeding vessel. Liquor ferri chloridi (five to ten drops in water every hour) is often employed, but is of extremely doubtful value. The baths can not be resumed till there has been no bleeding for at least three or four days—and then only cautiously.

If peritonitis occurs, the treatment is much the same. Above all, opium must be used in still larger doses, but, unfortunately, as a rule, in vain. Perhaps surgical treatment is destined eventually to be useful, viz., incision, cleansing, and drainage of the peritoneum. Its results thus far are not very encouraging.

If there is considerable diarrhœa, we can give *mistura gummosa* [P. G., gum arabic and sugar, each 15 parts; water, 170 parts], tannin, subnitrate of bismuth, or small doses of opium. Constipation at the beginning of the disease is overcome by calomel (*vide supra*). In later stages we always try enemata first, to

produce an operation. If this does not succeed, then we must employ rhubarb or castor-oil. Great tympanites may be diminished by laying cold wet cloths or ice-bags upon the belly. Considerable amounts of gas may often be removed by introducing a long rectal tube. As to puncturing the greatly inflated intestines, a method practiced by some physicians, we have no personal experience.

If there are severe pulmonary symptoms, baths and pouring on cool water are, as we have said, the best remedies. Internally we may try liquor ammonii anisatus [P. G., olei anisi, 1 part; aquæ destillatæ, 24 parts; aquæ ammoniæ, 5 parts] and benzoic acid (grains ij to iij, gramme 0.1 to 0.2, in powder). If the pulse be very rapid, we can put an ice-bag over the heart. If at the same time the pulse is small and weak, we give stimulants, of which the best is camphor (*vide infra*). Digitalis (one-half grain of the leaves, gramme 0.03, two or three times daily) may also be employed if the pulse be rapid; but it should be used with great caution.

For nervous symptoms the baths and douching are the most effective remedies. The head is meanwhile covered by an ice-bag. If there be great excitement, as shown by excessive restlessness or delirium, small doses of morphine are often very useful.

The conditions of collapse and cardiac failure, which sometimes appear rather suddenly, demand prompt and energetic treatment. Stimulants to be given internally are some stronger kind of wine, camphor (two to five grains, gramme 0.10 to 0.30, in the form of a powder), musk (one half grain to one grain, gramme 0.03 to 0.05 at each dose), or spiritus ætheris [P. G., æther, one part; alcohol, three parts]. Subcutaneous injections act quicker and are much more convenient. We may use either ether or camphor (one part camphor to four parts olive-oil, seven to fifteen minims, c. c. 0.5 to 1.0, every one to two hours). To start up respiration, the best means is to pour cold water on the back of the neck. Artificial respiration also succeeds, in many cases, in reviving the breathing when it is about to stop.

The numerous other complications and sequelæ which may occur, but which can not all be mentioned here, should be treated on general principles.

The prophylactic measures to avoid the spreading of the disease can be only briefly referred to. Of chief importance is careful disinfection of the excreta, which can be accomplished by pouring upon the stools a not too small amount of five-per-cent. carbolic solution. We should also take care that bed-pans, bed-clothes, linen, etc., are handled by other persons as little as possible. If there seems reason to suspect that the disease arose from bad water, of course the source of such suspected water must be cut off.

[Recent experiments tend to show that the above solution of carbolic acid does not kill spores except after prolonged contact.

The following are the measures of disinfection recommended by the American Public Health Association. It will be observed that they apply to all infectious diseases, and it seems well to give them here nearly *in extenso*, as the directions for disinfection in most text-books are far too vague.

*Disinfection of Excreta, etc.*—The infectious character of the dejections of patients suffering from cholera and from typhoid fever is well established; and this is true of mild cases and of the earlier stages of these diseases as well as of severe and fatal cases. It is probable that epidemic dysentery, tuberculosis, and perhaps diphtheria, yellow fever, scarlet fever, and typhus fever, may also be transmitted by means of the alvine discharges of the sick. In cholera, diphtheria, yellow fever, and scarlet fever, all vomited material should also be looked upon as infectious; and in tuberculosis, diphtheria, scarlet fever, and infectious pneumonia, the sputa of the sick should be disinfected or destroyed by fire. It seems

advisable also to treat the urine of patients sick with an infectious disease with one of the disinfecting solutions below recommended.

Chloride of lime, or bleaching powder, is, perhaps, entitled to the first place for disinfecting excreta, on account of the rapidity of its action. The following standard solution is recommended :

STANDARD SOLUTION No. 1.

Dissolve chloride of lime, of the best quality,\* in pure water, in the proportion of four ounces to the gallon. Use one quart of this solution for the disinfection of each discharge in cholera, typhoid fever, etc. Mix well and leave in vessel for at least one hour before throwing into privy-vault or water-closet. The same directions apply for the disinfection of vomited matters.

STANDARD SOLUTION No. 2.

Dissolve corrosive sublimate and permanganate of potash in pure water, in the proportion of two drachms of each salt to the gallon. This is to be used for the same purposes and in the same manner as Standard Solution No. 1. It is equally effective, but must be left a longer time in contact with the material to be disinfected—at least four hours. The only advantage this solution has over No. 1 consists in the fact that it is odorless. It costs about two cents a gallon. It is very poisonous, and will injure lead pipes if passed through them in considerable quantities. Solutions of corrosive sublimate should not be placed in metal receptacles.

*Disinfection of the Person.*—The surface of the body of a sick person, or of his attendants, when soiled with infectious discharges, should be at once cleansed with a suitable disinfecting agent. For this purpose solution of chlorinated soda, diluted with three parts of water, or Standard Solution No. 1, diluted with three parts of water, may be used. A two-per-cent. solution of carbolic acid is also suitable for this purpose, and, under proper supervision, the use of a solution of corrosive sublimate (1-1,000) is to be recommended.

In diseases like small-pox and scarlet fever, in which the infectious agent is given off from the entire surface of the body, occasional ablutions with solution of chlorinated soda, diluted with twenty parts of water, will be more suitable than the stronger solution above recommended.

In all infectious diseases the body of the dead should be enveloped in a sheet saturated with Standard Solution No. 1, or with a five-per-cent. solution of carbolic acid, or a 1-500 solution of corrosive sublimate.

*Disinfection of Clothing.*—Boiling for half an hour will destroy the vitality of all known disease-germs, and there is no better way of disinfecting clothing or bedding which can be washed than to put it through the ordinary operations of the laundry. No delay should occur, however, between the time of removing soiled clothing from the person or bed of the sick and its immersion in boiling water, or in one of the following solutions; and no article should be permitted to leave the infected room until so treated.

STANDARD SOLUTION No. 3.

Dissolve four ounces of corrosive sublimate and one pound of sulphate of copper in a gallon of water. Two fluid ounces of this standard solution to the gallon of water will make a suitable solution for the disinfection of clothing.

---

\* Good chloride of lime should contain at least twenty-five per cent. of available chlorine. The cost of the solution is less than one cent a gallon. The sediment does no harm.

The articles to be disinfected must be thoroughly soaked with the disinfecting solution, and left in it for at least two hours, after which they may be wrung out and sent to the wash.

Clothing may also be disinfected by immersing it for four hours in a two-per-cent. solution of carbolic acid. Soiled mattresses, pillows, feather beds, and articles of this nature can not be effectually disinfected by sulphur fumigation, owing to the fact that the gas does not penetrate to their interior in sufficient amount. For articles of this kind, and in general for articles of little value, which have been soiled by the discharges of the sick, destruction by fire will be advisable.

*Disinfection of the Sick-Room.*—No disinfectant can take the place of free ventilation and cleanliness, and it is impracticable to disinfect an occupied apartment. Neutralizing bad odors is not disinfection.

All surfaces should be thoroughly washed with Standard Solution No. 1, diluted with three parts of water, or with a 1-1,000 solution of corrosive sublimate. Standard Solution No. 3, diluted in the proportion of four ounces to the gallon of water, may be used.

The walls and ceiling, if plastered, should be brushed over with one of these solutions, and subsequently washed over with a lime-wash.

Especial care must be taken to wash away all dust from window ledges and other places where it may have settled, and thoroughly to cleanse crevices and out-of-the-way places. After this application of the disinfecting solution, and an interval of twenty-four hours or longer for free ventilation, the floors and wood-work should be well scrubbed with soap and hot water, and this should be followed by a second more prolonged exposure to fresh air, admitted through open doors and windows.

As an additional precaution, fumigation with sulphurous-acid gas is to be recommended, especially for rooms which have been occupied by patients with small-pox, scarlet fever, diphtheria, typhus fever, and yellow fever. All apertures into the room should be carefully closed, and not less than three pounds of sulphur for each thousand feet of air-space should be burned. To secure complete combustion, the sulphur, in powder or small fragments, and moistened with alcohol, should be placed in a shallow iron pan, and this should be placed on bricks in a tub partly filled with water to guard against fire.]

## CHAPTER II.

### TYPHUS FEVER.

(*Spotted Fever. Ship Fever.*)

TYPHUS fever is an acute infectious disease, perfectly distinct from typhoid fever, but formerly often confounded with it. The similarity of the two diseases, which led to their similar names, consists only in the grave general condition, with fever, and in a number of complications, which may appear in both. There is, however, an essential difference in the whole course of the diseases, and especially in the circumstance that the intestinal lesion which is characteristic of typhoid is never seen in typhus. The chief distinction between the two affections, which must undoubtedly lie in the difference in their causes, can not yet be demonstrated. We do not yet know the organized pathogenic agents of typhus fever, although it must be presupposed that they exist.

**Etiology.**—As to the way in which infection occurs, we have much less information even than in relation to typhoid. We regard it as an established fact that

the disease never arises spontaneously, and that its appearance in a place previously free from the disease is always to be referred to an importation of the pathogenic poison. It is likewise determined, through numerous observations, that typhus is one of the contagious diseases—that is, that the specific poison can be directly transferred from the patient to others around him. How it is transferred we have no certain knowledge. Perhaps the poison is contained in the expired air; or, as is still more probable, in the scales of epidermis; or, perhaps, in the other excretions and secretions of the patient. We are equally ignorant through what channel the infectious agent enters the system—whether it is inspired or swallowed. It is certain that the poison may be transferred in the clothes, etc., of the patient (fomites).

Favorable hygienic surroundings decidedly diminish the contagiousness of typhus fever. For example, in the well-ventilated pavilions of the Leipsic hospital there have rarely been cases of transfer of the disease to physicians, nurses, or other patients. On the other hand, if the hygienic influences be unfavorable, typhus fever may appear in very widespread epidemics. Those terrible epidemics which have been described under the names of "famine fever," "camp fever" (Hungertyphus, Kriegstyphus), etc., were for the most part typhus fever. In the smaller epidemics it is often possible to trace the disease to some wretched, over-filled tenement-house.

At present typhus fever appears constantly in Great Britain. Ireland has been notorious for many years as a breeding-place of the disease. It is also frequent in the eastern part of Germany (Posen, East Prussia and West Prussia, Silesia), in Poland, Galicia, Russia, and in parts of southern Europe. The isolated cases which occur every year here and there in central Germany, though more or less numerous, are, almost without exception, to be referred to an importation of the disease.

Typhus fever attacks by preference young adults of twenty to forty years; but it occurs in children, and is comparatively frequent in elderly persons. There is no marked dependence of the epidemics upon any particular season of the year. As in the case of typhoid fever, a person who has once had the disease seems to enjoy immunity from any fresh attack.

[The practical acquaintance of American physicians with typhus fever is, fortunately, limited. Many of the outbreaks which have occurred were traceable to immigrants, especially from Ireland.

During our civil war the disease broke out neither among the armies in the field nor among the prisoners of war. A number of cases were reported at the time, but great doubt has since been thrown upon the correctness of the diagnosis.]

**Course and Symptoms of the Disease.**—If we try to sketch the characteristic behavior of typhus fever, especially as contrasted with typhoid, we may say that the disease begins much more abruptly and rapidly, and that the fever quickly becomes very high and the general disturbance very severe, but the illness lasts a shorter time, seldom more than two weeks, and generally passes by crisis into recovery.

The length of incubation seems to vary. Murchison thinks it is usually more than nine days. Sometimes, though not invariably, slight prodromata precede by some days the actual outbreak of the disease. These are languor, anorexia, headache, and pain in the limbs. Then the regular illness begins, as a rule, rather suddenly, and often with a pronounced rigor. With this the temperature rises quickly, and may <sup>at evening reach 104° or 105°</sup> (40°–40.5° C.). Vomiting is <sup>attended.</sup> A grave general condition, with fever, is <sup>at feels exhausted.</sup>

There is often violent pain in the loins and extremities. Nervous symptoms soon appear: persistent and intense headache, vertigo, spots before the eyes, ringing in the ears, and in many cases quickly increasing stupor and delirium. In severe cases the fever often reaches  $106^{\circ}$  ( $41^{\circ}$  C.), and may be even higher, and it is almost constant, with but slight morning remissions. The skin is hot and dry, the tongue dry and thickly coated, the respiration moderate, the pulse very rapid. We very frequently find in the chest the signs of an extensive bronchitis. Nasal catarrh and conjunctivitis also occur. Serious intestinal symptoms are generally absent, although there may be slight tympanites or diarrhoea. The spleen is almost always greatly enlarged. Only in a few epidemics is the splenic tumor said to have been wanting (?). The urine is concentrated and scanty, and sometimes has a trace of albumen.

On the third to the seventh day of the disease the characteristic eruption appears. To this the disease owes its name of "spotted fever." The eruption consists of rose-spots, generally very numerous and widespread, upon the trunk and extremities, often also on the face. Sometimes the spots are larger, and may then bear great resemblance to a fresh eruption of measles. The skin between the separate rose-spots is not infrequently diffusely reddened. After two or three days the roseolæ become hæmorrhagic, and change into lighter or darker petechiæ. It is commonly only in the lighter cases that the rose-spots fade away without first becoming petechial. In rare though well-substantiated cases the eruption has been scanty, or even wholly wanting. Herpes does occur, but only seldom.

The fever begins to abate in light cases as early as the second week, coincidently with an improvement in the general symptoms. Often this change is indicated about the seventh day by a considerable remission in the temperature. On the other hand, in severe cases, all the symptoms grow worse. The weakness increases. The nervous derangement reaches the extreme of a severe "typhoid state," expressed either by marked stupor, which sometimes passes into complete coma, or by violent delirium. Lobular pneumonia attacks the lungs, and the fever continues with unabated violence. These symptoms may end with death, but in favorable cases they decline rapidly. Sometimes this decline is preceded by a great rise in temperature (*perturbatio critica*) on the fourteenth to seventeenth day, rarely a few days earlier or later. In such cases the temperature is apt to fall by crisis, sinking in a day or two, with but slight interruption, down to the normal level. Even in those cases in which the descent is by gradations it is always decidedly more abrupt than in typhoid. The eruption quickly fades, the patients gradually improve, and, as a rule, become completely and permanently convalescent. It is true that some observers have seen relapses, but they are, at least in our present epidemics, extremely rare.

**Complications and Varieties in the Course of the Disease.**—From what we have said of its course, it is evident that the symptoms are essentially those of an intense general infection of the system. The sole demonstrable local lesion which is almost invariably present is the characteristic eruption, and this has evidently no causal relation to the severe symptoms of the disease. It is likewise extremely probable that most of the complications, which not infrequently arise in severe cases, are secondary, and occur in the way already described with considerable detail in the preceding chapter. They are just such complications as are possible in every severe general disease, and embrace otitis, parotitis, extensive lobular pneumonia, more rarely gangrene of the lungs, and pleurisy; also furunculosis, purulent cellulitis, bed-sores, dysentery, icterus, etc. Whether some of the local lesions which are observed may not be direct results of the pathogenic poison, we can not at present decide. Among these would come, first of all, the rare cases of lobar pneumonia and nephritis. Sequelæ are, on the whole, rare,

though sometimes there is a tedious anæmic condition, or neuralgia, paralysis, etc.

The separate epidemics of typhus present considerable variety, not only as regards the occurrence of individual complications, but more especially in the general course and character of the cases. For instance, some epidemics are distinguished by the greater frequency of light attacks (*typhus exanthematicus levissimus*, unsuitably termed by some "febricula"). Here the entire attack runs its course in five to eight days. The fever is generally comparatively moderate; there are no severe general symptoms, and complications are exceptional.

**Diagnosis.**—It may be very difficult for a time to distinguish typhus from typhoid. The following factors are of chief importance: 1. The onset is much more abrupt in typhus than in typhoid, and is often accompanied by a pronounced rigor. 2. In typhus, the nervous disturbances usually appear earlier and are more severe than in typhoid. 3. The rash is seldom so extensive in typhoid as in typhus, and in typhoid it hardly ever becomes petechial. 4. In typhus the pains in the loins and limbs are generally much more pronounced. 5. If we still find it hard to decide, the manner of recovery will almost always settle the question. Recovery in severe cases of typhoid is, on the average, much more tardy and gradual, by lysis. In typhus it occurs generally by the seventeenth day, and by crisis.

The **prognosis** is chiefly determined by the severity of the fever and of the nervous symptoms. Extensive lobular pneumonia is the most frequent dangerous complication. The mortality varies greatly in the separate epidemics. It is sometimes only six or seven per cent., but may rise to twenty per cent.

**Treatment** is based on the same principles as in typhoid fever. There is no specific remedy. Besides good nursing, a judicious employment of baths is certainly our chief reliance for lessening the severity of many of the symptoms, such as febrile, nervous, and pulmonary disturbances, as well as for averting many dangerous complications. For all details of treatment we may refer to the preceding chapter.

### CHAPTER III.

#### RELAPSING FEVER.

(*Relapsing Typhus*—*Febris recurrens*.)

**Ætiology.**—This disease was first named by English pathologists relapsing fever, and by Griesinger *febris recurrens*. It has a peculiar course, made up of separate attacks, and is further of great interest because it is one of the first infectious diseases in which the specific pathogenic organisms became known, and, being easily demonstrable in each separate case, were utilized for the speedy and certain diagnosis of the disease. Obermeier discovered in Berlin, in the year 1873, that in relapsing fever the blood, at certain times, invariably contains peculiar, thread-like micro-organisms. This discovery has since been universally confirmed; and it may be maintained that if once the presence of these "spirilli" be demonstrated in the blood, we are justified in making an absolute diagnosis of relapsing fever.

In Germany the disease did not become epidemic till the year 1868. In 1872 and 1873 there were considerable epidemics in Breslau and Berlin. Its last extensive appearance was in 1879 and 1880, when it spread over most of northern and central Germany, and was accurately studied by numerous observers. People of

the poorer classes were almost exclusively attacked, and especially the "tramps." The uncleanly dens where these people lodge were found everywhere to be the chief centers of infection.

The precise manner of infection is as yet almost wholly unknown. All observers agree that the disease is directly contagious; but it can not be very contagious if the hygienic influences be good. At least the results of our late epidemics would imply this. In the Leipsic hospital, where over two hundred and fifty cases were treated, and isolation could not be at all perfectly carried out, not one case of infection occurred. It is certain that the disease can be transmitted by direct inoculation with the blood of patients. This has been established by a Russian physician by the experimental inoculation of healthy persons. Doctors have been repeatedly inoculated at the autopsy of those who have died of relapsing fever. The disease may likewise be transferred by inoculation to monkeys, while other mammals seem to enjoy an immunity from it.

[The first cases of relapsing fever observed in this country were in Irish immigrants coming over in the same vessel in the year 1844. At several periods since then more or less limited outbreaks traceable to immigration have occurred, but the disease has never acquired any foothold with us, and comparatively few physicians have ever seen it. So far as I can learn, only one case has ever been seen in Boston, and that was in the person of a physician from another city, who brought the disease with him and passed through it in the Massachusetts General Hospital.]

**Clinical History.**—The stage of incubation lasts about five to eight days. It is only exceptionally that some slight prodromal symptoms present themselves just before the outbreak of the disease proper. As a rule, it begins suddenly, with a more or less pronounced chill and intense constitutional symptoms. There are violent headache, great languor, anorexia, and especially marked pains in the loins and extremities. The temperature rises rapidly, reaching generally  $106^{\circ}$  ( $41^{\circ}$  C.) or higher as early as the first or second day. The skin is hot and dry, and usually quickly assumes a very characteristic dirty-yellowish color. In Leipsic, we often saw herpes labialis, which seems, however, to have been rarer in epidemics elsewhere. The tongue becomes dry and thickly coated. Sometimes there is vomiting. The bowels are constipated, or there is a slight diarrhœa. The spleen becomes rapidly enlarged, being, as a rule, even larger than in typhoid or typhus. The liver is slightly enlarged. The chest presents the signs of a bronchitis, generally moderate, but in exceptional instances severe. The pulse is much quickened. It is seldom that there are severe cerebral symptoms beyond a certain apathy and stupor. We have seen delirium tremens sometimes, in drunkards. A very characteristic symptom, already mentioned, is the marked hyperæsthesia of the muscles, especially in the calves.

After these symptoms, accompanied by persistent and generally very high fever, have lasted five days to a week, there is a critical decline of temperature, with profuse sweating. The patient now improves so rapidly and decidedly that he thinks himself completely cured, and generally gives little credence to the physician's prophecy of a relapse. In rare but well-attested cases there has been really but one attack. The rule is that, after about a week, a second attack occurs, often a third after that, and, infrequently, even a fourth and fifth. In each of these, the above-mentioned symptoms are repeated more or less completely and violently. As the only certain and constant sign of the recurring attacks (the so-called relapses) is a fresh rise of temperature, it will be well to consider their peculiarities at the same time that we describe the course of the fever. During the intervals of normal temperature the other objective symptoms of disease are usually absent, except an evident splenic tumor, and, not infrequently, the peculiar pale-yellow hue.

COURSE OF THE FEVER (see Fig. 3).—The beginning of the fever in the first attack is, as we have said, almost always sudden, so that it may even in a few hours reach a considerable height. The fever lasts, as a rule, five to seven days, but not infrequently as short a time as three or four days, or as long as ten or twelve days. During this time it may keep a tolerably uniform height, but oftener there are considerable remissions, which may even come to deserve the name of pseudo-crises. In such cases the temperature sinks in the morning to normal or even lower, so that we might believe the fever ended; but in the evening the temperature rises again to its former level. These pseudo-crises are most frequent toward the end of the attack, but do occur sometimes in the very first days. The absolute height of the fever is, as a rule, very considerable. Temperatures between  $105.5^{\circ}$  and  $106.5^{\circ}$  ( $41^{\circ}$  and  $41.5^{\circ}$  C.) are very often observed, and in themselves are not especially ominous in relapsing fever. The highest temperature we have observed was  $107.9^{\circ}$  ( $42.2^{\circ}$  C.). Sometimes the temperature is more moderate (between  $102^{\circ}$  and  $104^{\circ}$ ,  $39^{\circ}$  and  $40^{\circ}$  C.). The fever almost always ends at the close of the attack by crisis, only rarely by a rapid, gradual decline. The crisis is often preceded by an especially great rise the evening before (*perturbatio critica*); so that the subsequent fall of temperature is very considerable. It generally occurs at night, and is accompanied by profuse perspiration. The fall may amount to  $9^{\circ}$  or  $10^{\circ}$  ( $5^{\circ}$  to  $6^{\circ}$  C.). The temperature sinks almost always below normal, often as low as  $95^{\circ}$  ( $35^{\circ}$  C.) or thereabouts. Once we saw it fall to  $92.1^{\circ}$  ( $33.4^{\circ}$  C.).

To the first attack succeeds an interval during which there is no fever (apyrexia), which lasts on the average about a week, sometimes a less time, and often a greater. The longest interval we have ever observed lasted seventeen days.

FIG. 3.—Example of the temperature curve in relapsing fever.

During this interval the temperature, which, as a rule, is at first subnormal, rises to normal, and then generally remains there. Exceptionally there are slight evening exacerbations to above  $100.5^{\circ}$  ( $38^{\circ}$  C.). These may have no demonstrable cause, or may result from some complication, such as otitis, or a furuncle. Then comes another change, and generally a sudden one, ushered in with a chill, and a new rise of temperature, the beginning of the second attack or first relapse. During this attack the fever has the same general peculiarities as in the first attack. Generally the first relapse is briefer by a day or two than the first attack; but the reverse is sometimes true. We will add that we have observed not infre-

quently a rather high evening temperature (say  $101.5^{\circ}$ ,  $38.5^{\circ}$  C.) for one or two days before the second attack began, as also before the third.

Relapsing fever seems in many epidemics to have been made up of two attacks, so that not more than one tenth of the cases had a third attack. On the other hand, the majority of the cases in the last epidemic had two relapses. And in these cases the rule was for the interval between the second and third attacks to be one or two days longer than the first apyrexia; but earlier epidemics seem to have had the second apyrexia, if there was one at all, briefer than the first. The third attack is set down in all reported cases as decidedly shorter than either of its predecessors. It lasts generally two or three days. Exceptionally we have seen it persist for four or even six days.

A fourth and even a fifth attack may occur, but only exceptionally. If they do happen, they are usually imperfectly developed, and often are limited to a fever of one day's duration. The more accurately and persistently we take the temperature during convalescence, the oftener do we find slight rises of temperature occurring at intervals late in the history of the case. These are probably to be interpreted as final, rudimentary attacks.

**THE SPIRILLI.**—The number of cases of relapsing fever in which no spirilli can be demonstrated in the blood, if the examination be accurate, has become so small that it can be disregarded when we compare it with the much greater number of cases where such demonstration is made with ease and certainty. The best way is to get a drop of blood by pricking the skin, and examine it as it is, without mixing anything with it. There is no need of an immersion lens. With a good Hartnack No. 8 [about 330 to 440 diameters, according to eyepiece] the spirilli are seen with perfect distinctness. We have often seen them plainly with a No. 7 [250 to 340 diameters]. It requires a little practice to make them out; but this is easily obtained. Often the attention is first caught by little joggings and motions of the red blood-corpuscles, and then we see the delicate, narrow threads. Their length equals about three to six times the diameter of the red globules (Fig. 4). They exhibit an active and almost continuous motion, like snakes. Often the whole thread bends upon itself, and then stretches out again. They are partly separate and partly tied up in knots composed of four to twenty individuals. The whole number visible in one field varies greatly in individual cases, and has no direct

FIG. 4.—Spirilli of relapsing fever in the blood.

relation to the severity of the case. Often it requires long searching to find a few, while in other cases there may be twenty or more in the field at once. A very interesting fact is that their appearance in the blood depends upon the attacks of fever. On the first day of the attack we rarely find spirilli, and then only one or two. Upon succeeding days their number increases. Shortly before the end of the attack—that is, before the crisis—they generally disappear entirely; but even after the crisis they have been found, exceptionally and in very small numbers. They have very often been found by the author as well as other observers during the pseudo-crisis described above, so that, after the temperature has become normal, the presence of spirilli makes it very probable that another rise of temperature is impending. The spirilli have thus far been found in the blood only, in the catamenia, in bloody urine, or in blood coughed up from the lungs, and

never in the organs or secretions (urine, milk, sweat, contents of herpetic vesicles). There can hardly be any doubt that the spirilli which appear in the separate attacks are to be regarded as separate generations. As to their manner and place of development we have as yet no knowledge. In the final, rudimentary attacks, we find few if any. If the patient dies during an attack, they are to be found in the blood after death. Artificial cultivations have not been very successful; nor have pure cultures of them, to our knowledge, ever succeeded. Albrecht states that they will subsequently develop in blood taken from a patient during the interval when he has no fever.

The blood is otherwise modified during relapsing fever. We very often find a slight increase in the white corpuscles. There is often a noticeable abundance of very small bodies, so-called granular elements (*Körnchenbildungen*). The significance of these (the remains of white corpuscles?) is still doubtful. There are, finally, peculiar cells, rather large, with fat-granules. They were demonstrated by Ponfick in the venous blood, and are said to come from the spleen. We also find fatty-degenerated endothelium in the blood.

**Complications** are on the whole rare, and mostly secondary. Important among these are troublesome ophthalmic disturbances, especially iritis and iridochoroiditis. Sometimes parotitis, laryngitis, and pneumonia occur. Epistaxis is a not infrequent complication. It is usually profuse and persistent, and may even be dangerous. Sometimes there has been rather severe dysenteric trouble. In one case which ended fatally we observed a very peculiar intestinal lesion, consisting of hæmorrhagic-necrotic foci in the colon and lower ileum. In severe cases acute hæmorrhagic nephritis occurs with comparative frequency. At the autopsy an important and characteristic phenomenon is the wedge-shaped white spots which occur in the spleen, like infarctions. They have a clinical interest, as they may become the starting-point of pyæmic conditions or of peritonitis. Splenic abscesses have been observed in a few cases.

**Variations in the course of the disease** occur in this, as in all other acute infectious diseases. First there are mild, abortive cases, in which the attacks are few and brief. Then cases have been described resembling intermittent fever. Of chief importance is that severe variety of relapsing fever first observed in Egypt by Griesinger, and described as "bilious typhoid." There is no longer any doubt about the proper classification of this disease, for spirilli have been proved to appear in it, and it has even been shown that its inoculation upon another person (!) produces a common case of relapsing fever. Bilious typhoid fever occasions successive attacks, like those of relapsing fever. The type is much more severe. As a rule, there appear marked icterus, grave nervous symptoms, hæmorrhages into the skin and mucous membranes, and the termination is frequently fatal. The autopsy shows a greatly enlarged spleen, often containing infarctions and abscesses, and in some cases hepatic abscesses, septic nephritis, and similar lesions.

The **prognosis** of ordinary relapsing fever is on the whole very favorable. In the last epidemics the usual mortality was only two to four per cent. The fatal cases could some of them be laid to wretched nursing. In the remaining portion death resulted from complications, such as pneumonia and nephritis.

The **treatment** must as yet be purely symptomatic. Antipyretic treatment is generally needless, since the fever is relatively brief and often quite intermittent. Moreover, most patients can not well endure cold baths, because the muscles are so painful. As a rule, good nursing and proper food amply suffice. If the muscular pains are very violent, we may order chloroform liniment as an embrocation. Complications are to be treated on general principles.

We are not acquainted with any remedy that can influence the disease itself

or avert the relapses. Large doses of quinine, salicylic acid, etc., have been frequently employed for this purpose, but never with success. Lately there has been ascribed to calomel a favorable influence upon the general course of the disease, and its use is said to diminish the number of attacks. We must await further evidence in support of this statement.

---

#### CHAPTER IV.

##### SCARLET FEVER.

(*Scarlatina.*)

WE now begin the consideration of those acute infectious diseases which are usually embraced under the name of the "acute exanthemata." In this group are reckoned, besides scarlet fever, measles, r  theln, small-pox, varicella, and sometimes also facial erysipelas. The point which these diseases have in common is that in all of them is developed a characteristic eruption, of slight clinical significance in itself, in most cases, but of thoroughly characteristic appearance in each disease, and hence of essential importance in diagnosis. A number of the acute exanthemata have this further point of mutual resemblance that they appear chiefly in children. These diseases are scarlet fever, measles, r  theln, and varicella.

**  tiology.**—Infection with the specific scarlatinal poison occurs almost always by contagion, which takes place very readily. A single approach to a patient ill with scarlet fever may suffice to communicate the disease. There is no doubt that the disease may be transferred by objects which the patient has touched, such as linen, clothing, furniture, or toys. Persons who have been with the sick may be the means of transmitting the disease, although themselves unaffected. In England it has been thought that the contagium may be carried by milk.

Numerous observations show that the scarlatinal poison is with great difficulty destroyed, and may keep its contagious powers for months ("tenacity"). We can thus see how difficult, how impossible, it may be in an individual case to point out the source of contagion. Scarlet-fever patients can communicate the disease certainly as late as the end of the desquamative period.

Details as to the manner of contagion, or as to the specific poison itself, are as yet unknown. There have been repeated statements about the presence of bacteria in the blood and in the tissues of scarlatinal patients; but it is very improbable that the specific poison of scarlet fever has been observed. This poison must, however, be contained in the blood, and in the contents of the miliary vesicles, of scarlet-fever patients, for the disease has repeatedly been artificially produced in healthy persons by inoculation with these fluids.

Predisposition to scarlet fever is far less universal than is predisposition to measles or small-pox. In families with several children often only one or two fall sick, while the rest escape, although equally exposed. As age increases, liability to the disease greatly diminishes, although there are cases of scarlet fever among adults. The majority of patients are between two and ten years of age. Scarlet fever is rare during the first year of life. It is an interesting fact that children with fresh wounds, either accidental or surgical, are especially liable to scarlet fever. An analogous and familiar fact is that women after delivery have a strong tendency to the disease.\* With very few exceptions a person is attacked but once,

---

\* In puerperal cases genuine scarlet fever and septic diseases were formerly often confounded. (See Chapter XVIII.)

so that, after the disease is over, an immunity from contagion is enjoyed; but there are exceptions to this rule.

Scarlet fever is now spread over the entire globe. Here in Germany there are almost always some sporadic cases in the larger towns, while from time to time, especially in autumn, there are more or less extensive epidemics in one place or another. There is considerable variation in the different epidemics of scarlet fever, as in many other infectious diseases, in the general character of the disease, and above all in the prevailing mildness or severity of the cases.

**Clinical History.**—The period of incubation is about four to seven days, or is sometimes apparently shorter. There are hardly ever any decided prodromata. The disease begins rather suddenly, with fever, often introduced by chilliness, and sometimes by a well-marked rigor. There is almost invariably a painful, scarlatinal sore throat. A further symptom, in all cases of any severity, is cerebral disturbance, generally rather intense. There may be headache, dullness, uneasy sleep, delirium, and, in smaller children, sometimes even convulsions. A very frequent and characteristic early symptom is vomiting, which may be repeated.

The characteristic rash usually appears as early as the close of the first day, or on the second, and begins on the neck and on the chest and face, soon becoming almost universal. The eruption consists at first of numberless small red points, crowded thickly together and soon united into a diffuse, intense, scarlet-colored erythema. The small and somewhat elevated points almost always correspond to the swollen hair-follicles. The diffuse redness is the result of an excessive hyperæmia of the skin, and vanishes completely on pressure. The back usually presents the most vivid tint. In the face there is generally pallor of the lips and chin, presenting a very striking and characteristic contrast to the bright-red cheeks. If some object like the end of a pen-holder be drawn over the red skin, there soon arise corresponding white lines, due to contraction of the blood-vessels. It is possible thus to make letters or pictures upon the back of the patient. We should add, however, that this is not a peculiarity of the scarlatinal eruption, being seen in other erythematous eruptions.

The rash persists for some three or four days, at first even increasing somewhat in vividness. It often appears more intense by artificial light than in the daytime. Meanwhile the severe general symptoms continue—the fever, the usually excessively rapid pulse, the cerebral symptoms, and the throat trouble. The spleen is often somewhat swollen, though seldom very large. Then the eruption begins to fade, the fever gradually ceases by lysis, the general condition and the difficulty in swallowing improve. With the end of the first week or the beginning of the second, the cases which run the typical course become fully convalescent. When the rash disappears, the epidermis usually begins to peel off, in a very characteristic way, in pieces of considerable size. The exfoliation upon the hands and feet is especially pronounced, and the little convalescents often amuse themselves by peeling off the epidermis in strips. Cases which are apparently the mildest and most benign may have their convalescence interrupted by the occurrence of a secondary scarlatinal nephritis. There is no certain prophylaxis against this.

We will now pass on from this general summary to a more complete consideration in detail of general and local symptoms. And we shall see how manifold are the clinical phenomena presented by scarlet fever.

1. *Fever* (see Fig. 5).—Although in a few undeveloped cases there is no fever, or scarcely any, almost all cases of any importance have high fever. It is only exceptionally that severe cases are observed where the bodily temperature is little if at all elevated. As a rule, the fever rises rapidly upon the very first day, corresponding to the sudden onset of all the symptoms, to about 104° or 105° (40°–40·5° C.). The next day it often becomes a little higher still, and then persists

with but slight variations, as a rule, so long as the eruption is at its height. During this period a temperature of  $105^{\circ}$  or more ( $40.5^{\circ}$ – $41^{\circ}$  C.) is not infrequently

FIG. 5.—Example of a normal scarlet-fever curve.

observed. When the eruption fades, and the other symptoms decline, defervescence occurs. This happens but rarely by crisis, and that in the slight attacks. It is almost always by prolonged lysis, as in typhoid, only more irregularly and more rapidly. If the fever lasts into the second week of the disease, it is almost always (though not without exceptions) caused by demonstrable complications. The most frequent causes are the persistence of a severe sore throat, the occurrence of inflammatory changes in the cervical glands, or a purulent otitis media. In closing what we have to say about the fever in this disease, we would empha-

size the fact that the pulse is often very rapid, even considering the height of the temperature.

2. *The Throat.*—The throat presents the most constant local lesion of scarlet fever. Sore throat is only in the rarest cases wholly absent; but its form and intensity may vary extremely. The mildest variety is a simple, erythematous catarrh, without much swelling, but exhibiting a more or less intense reddening of the soft palate and tonsils, frequently associated with enlargement of the little mucous follicles. Sometimes minute hæmorrhages take place into the mucous membrane. In other cases the scarlatinal affection of the throat is from the start associated with considerable swelling of the parts, and especially of the tonsils, justifying the term "parenchymatous sore throat." Not infrequently small abscesses form in the lacunæ of the tonsils or superficial spots of necrosis develop which leave behind them larger or smaller ulcers, and sometimes occasion considerable hæmorrhage. There may even be a circumscribed gangrene of the tonsils.

By far the most important, because it is also the most dangerous, of the affections of the throat resulting from scarlet fever is the so-called scarlatinal diphtheria—that is, a diphtheritic inflammation of the tonsils and soft palate. This usually develops on the third, fourth, or fifth day of the disease, replacing a simple inflammatory condition of the parts. Whitish, dirty-colored spots develop on the tonsils, the arches of the palate, and the uvula. These rapidly increase in size, and cause a dry necrosis of the mucous membrane and subsequent ulceration. The process is a truly diphtheritic one—that is, there is an inflammation combined with an extension into the diseased tissues of a fibrinous exudation.

It is especially characteristic of scarlatinal diphtheria that there is almost invariably a considerable swelling of the cervical lymph-glands, except in those cases which die very quickly. It is true that the glands are usually somewhat enlarged in the milder forms of pharyngitis accompanying scarlet fever, but they seldom attain the size observed in the true diphtheritic process. In this there is an inflammatory and œdematous infiltration affecting often not only the glands themselves, but also the surrounding connective tissue, so that in severe cases the whole cervical region and the floor of the buccal cavity presents a firm and usually a very painful enlargement. It should be added that the severity of the throat symptoms and the extent of the glandular swelling are not always com-

mensurate. Almost always the scarlatinal diphtheria is associated with a marked stomatitis, and very often also with a severe purulent or even diphtheritic rhinitis. At the alæ of the nose and the corners of the mouth there are often superficial ulcers from this cause. Otitis is also a frequent complication of scarlatina (*vide infra*). The swelling of the lymph glands in the throat very often terminates in suppuration. The influence upon the general condition of the patient of the scarlatinal diphtheria is apt to be considerable, apart from the marked local discomfort. The constitutional symptoms are often as severe as in septicæmia or pyæmia. Many cases end fatally in a few days, while others pursue a more tedious course, lasting perhaps several weeks before death comes. These are often associated with pyæmic processes in other parts of the body.

With regard to the pathogenesis of the throat troubles seen in scarlet fever, the more simple forms are in all probability directly associated with the scarlatinal process—that is, they are direct sequences of the affection. As relates, however, to the severer forms, and in especial the diphtheritic variety, it is at least very probable that these are not a direct result of the scarlatinal poison, but are due to some secondary infection which takes place at the spot of the primary scarlatinal angina. But we are almost obliged to suppose that there is some intimate connection between the two varieties of infection, else why should this peculiar secondary disease, the scarlatinal diphtheria, be so often conjoined with scarlet fever? Yet the fact deserves emphasis that the diphtheria seen in scarlet fever has no ætiological connection with genuine primary diphtheria (see the chapter on this latter disease), although the pathological anatomy is almost the same in both diseases. From a clinical standpoint the two present several important points of difference. In particular the scarlatinal diphtheria, in contrast with the primary form of the disease, seldom spreads to the larynx. Laryngeal croup is therefore but rarely seen in scarlet fever, and perhaps when it does occur it is to be explained by an actual complication of the scarlatina with genuine diphtheria. The severe dyspnoea which sometimes develops in the course of scarlet fever is probably caused by an inflammatory œdema of the glottis. Another important clinical distinction between genuine and scarlatinal diphtheria is that paralysis of the soft palate, the ocular muscles, and other parts is scarcely ever a sequel of scarlatinal diphtheria.

The definitive answer to the question of the primary and the secondary varieties of infection in scarlet fever must be postponed until the individual germs corresponding to the same are accurately known. At present we have but a single noteworthy item of information, which is that there is present in scarlatinal diphtheria a peculiar "chain-forming micrococcus," discovered by Löffler in the necrotic mucous membrane, the lymph-glands, and even in the blood. This, perhaps, is the occasion of the secondary disease.

It may be added that, in puerperal scarlet fever, affections of the throat are noticeably infrequent or trivial, but the same question arises whether here scarlet fever and other diseases have not been confounded.

In addition to the redness there is often a variable degree of swelling. These latter cases form a connecting link between the ordinary variety and those cases of parenchymatous sore throat where the tonsils are intensely swollen and the soft palate and uvula are more or less œdematous. There may be small suppurating spots in the crypts of the tonsils, or these organs may suffer from larger abscesses, necrosis, or even gangrene. When the necrosed portions slough off, there may in rare cases occur a considerable hæmorrhage from the surface. Often chronic hypertrophy of the tonsils remains after these severe inflammations.

These graver varieties are almost always accompanied by sw

maxillary lymph-glands. The neighboring connective tissue will then often present diffuse infiltration and oedematous swelling. This swelling may in severe cases involve the floor of the mouth and the entire neighborhood of the throat. The severity of the trouble in the throat does not always correspond to that in the lymph-glands. Very frequently the swelling of the lymph-glands and the neighboring structures ends in the formation of abscesses.

The croupous and diphtheritic inflammations of the throat are the most important and justly the most feared. We believe that it is a mistake to speak of a "complication of scarlatina with diphtheria." The diphtheria of scarlet fever has, from an aetiological point of view, no relation to the common genuine diphtheria. It is a throat trouble having a direct connection with the scarlatinal process as such. It can, indeed, from its outward appearance,\* be distinguished with difficulty, if at all, from the primary, genuine variety (*q. v.*); and therefore, from an anatomical point of view, it must be termed a croupous or diphtheritic inflammation.

Scarlatinal diphtheria may be united with any of the above varieties of angina, either appearing at the very beginning of the illness, especially in very severe cases, or not till later, at the end of the first or even in the beginning of the second week. It is almost always the sign of a severe attack, and is therefore generally associated with high fever and grave general symptoms. The secondary swelling of the cervical lymphatic glands and the surrounding connective tissue generally attains a severe grade, and it is often very painful. Here, as in the other varieties of severe angina, there is almost always a simultaneous, intense stomatitis, and frequently a purulent coryza. There are often superficial ulcers on the *alæ nasi* and at the corners of the mouth. This form of diphtheria has one peculiarity of great interest and clinical importance. Unlike primary diphtheria, it seldom extends to the larynx, so that it is only in rare cases of scarlet fever that there are symptoms of laryngeal croup. A further important clinical difference between these two forms of diphtheria is that in scarlet fever there is scarcely ever any subsequent paralysis of the soft palate or of the muscles of the eye. A dangerous, but fortunately a rare, complication is oedema of the glottis. This may quickly cause death from suffocation. We may finally mention that puerperal scarlatina is said to have in many cases extremely slight throat complications, or none whatever.

3. We proceed by a natural sequence to the consideration of the affections of certain parts adjacent to the throat, troubles which must be regarded as chiefly the result of direct extension, or of a conveyance of the inflammatory process from the throat.

The stomatitis we have already mentioned, as well as the disturbance in the neighboring lymph-glands† and the surrounding tissue. Parotitis is not rare in severe cases. Of especial importance is the scarlatinal inflammation of the middle ear, which often results in permanent deafness.

This inflammation usually arises at the time of desquamation, but it may occur earlier. It is either a simple catarrh of the middle ear, or, in severe cases, an actual diphtheritic process. The deafness and earache are easily overlooked, as the other symptoms of the patient occupy the attention, so that the ear trouble is first recognized by the occurrence of perforation of the tympanum and subsequent purulent otorrhoea. After this declines there very often remains behind, as we

---

\* In microscopic preparations, however, according to Heubner's investigations, there are evident differences between genuine primary diphtheria and that of scarlet fever.

† It should be remarked that not infrequently there is also in scarlet fever a slight universal swelling of the lymph-glands (back of the neck, axilla, groins, etc.).

have said, permanent deafness. Statistics have shown that four or five per cent. of all cases of deafness are referable to an attack of scarlet fever in childhood. The otitis is seldom immediately dangerous, but yet cases of purulent meningitis have been observed to follow it.

We have already spoken of the purulent or even diphtheritic rhinitis which almost always accompanies the scarlatinal sore throat. In rare cases there may also occur a purulent conjunctivitis, which is most probably the result of a direct conveyance of inflammatory secretions.

The tongue in scarlet fever deserves special mention. The first coating cleans off, and then the tongue usually presents a very characteristic appearance. It is diffusely reddened and covered with little elevations corresponding to swollen papillæ (strawberry tongue, scarlatinal tongue).

1. The characteristic eruption, as developed in the great majority of cases, has been described above. It remains to describe certain variations from the usual appearances.

First, the eruption may be rudimentary. It is then not pronounced, and visible only on a limited portion of the body (face, trunk, or extremities).

Variations from the type are not rare; sometimes the papules are more strongly developed (*scarlatina papulosa*); very frequently there are little vesicles (*scarlatina miliaris*). This latter form of the eruption appears by preference upon the trunk, but it also may come upon the extremities, and is often brought out by excessive perspiration, or by wrapping up the patient too warmly. Many epidemics are noticeable from the frequent appearance of this miliary form. More rarely the rash has a spotted look, resembling the eruption of measles (*scarlatina variegata*). There may be minute ecchymoses, which are not ominous. Well-developed cases of hæmorrhagic scarlatina are, however, very dangerous, because here the general infection of the system is almost always exceedingly severe; and there is besides, as a rule, a general hæmorrhagic diathesis. Other cutaneous lesions, especially herpes and urticaria, are not so very unusual in connection with the scarlatinal eruption. Furunculosis has been repeatedly observed after the rash fades.

Desquamation generally begins as soon as the rash has completely disappeared, but may not occur till a few days or even one or two weeks later. Its extent corresponds in general to the severity of the eruption, although extensive desquamation may follow a rudimentary eruption. It is seldom bran-like or furfuraceous, as in measles. The rule is for it to be in lamellæ, so that, as we have stated, quite large strips of epidermis may be detached entire.

In rare cases an œdema of the skin appears after scarlet fever, which can not be shown to depend upon nephritis (*vide infra*), but may perhaps be due to an abnormal permeability of the walls of the cutaneous blood-vessels following the eruption (*hydrops scarlatinus sine nephritide*).

*Kidneys.*—Next to the severer forms of throat trouble, the most important and dangerous complications are located in the kidneys. They may appear as early as the acme of the disease, as in many other infectious diseases. The urine has a trace of albumen. In rare cases the amount of albumen may be considerable. The appearance of the urine is generally not much changed, and the microscope reveals but few abnormal constituents. There are some white and red blood-globules, a few hyaline casts, sometimes one or two renal epithelial cells. This initial albuminuria very rarely gives cause for alarm.

The genuine scarlatinal nephritis scarcely ever develops much before the end of the second or the beginning of the third week. Sometimes it comes even later. In one case under our own observation it did not begin till the thirty-third day of the disease. It may therefore be regarded to a certain degree as a late

lapse. It may be so mild as to cause no subjective symptoms whatever, and would be unnoticed if the urine were not carefully examined. On the other hand, it may be accompanied by the gravest symptoms, and soon terminate fatally. It may follow either severe cases or the mildest, so that the rule should be to examine the urine in every case of convalescence from scarlet fever as often and as accurately as possible. No exact statement can be made as to the frequency of this complication, for it is much more common in some epidemics than in others.

The development of nephritis is often marked by a fresh rise of temperature. The elevation may be slight or it may reach  $104^{\circ}$  ( $40^{\circ}$  C.). According to our own experience, the fever often comes a day or two earlier than the changes in the urine. As the nephritis goes on, it is very often accompanied by a moderate fever with remissions. This fever may be almost wholly absent, especially in mild cases. The pulse generally becomes harder, and is sometimes quickened; but in many cases it will be slow, and it is sometimes irregular. Among other objective symptoms, the first to excite notice is generally a slight puffiness of the face, which is usually pale. The eyelids, particularly, present an evident œdema. In the milder cases this œdema remains limited, while in others it gradually increases in extent and degree, involving first, as a rule, the dependent parts of the trunk, and later the extremities. Severe cases develop a pronounced anasarca. There are then, usually, effusions into the serous cavities, especially ascites and hydrothorax. The hydrothorax is frequently combined with severe bronchitis, and then may occasion extreme dyspnoea.

The urine exhibits the most important changes. These may be insignificant in the milder cases, but are very pronounced in the severe ones. The amount is much diminished. Sometimes there will be for several days almost complete anuria. In cases of any severity the urine is turbid, dark, often evidently bloody, with increased specific gravity (about 1015 to 1025), and containing a large amount of albumen. The sediment is generally abundant, and exhibits numerous hyaline casts of various lengths and diameters. To these may be attached red or white blood-corpuscles, detritus, granules of hæmatoidin, or bacteria. In cases of some duration the casts are often moderately fatty. Very frequently there are found noticeably long and broad waxy casts, which are opaque and yellow. In many cases of scarlatinal nephritis the urine is peculiar in having very many white blood-corpuscles, either isolated or adhering to the casts. These undoubtedly originate for the most part in the kidneys. Red globules, some of them in the form of colorless rings, are found. They are usually present in small numbers, but may become more abundant, especially for a day at a time. Renal epithelium is frequently seen, but not invariably nor in very large amount. It must be mentioned, in conclusion, that in some rare instances the autopsy discloses quite a marked nephritis, although the urine was apparently normal during life, or at least was not very abnormal.

Uræmic symptoms are not infrequent. They may be of all degrees of severity. They will be described in detail under diseases of the kidney (*vide infra*). The uræmia may be so severe as to cause convulsions, coma, and death; but it is remarkable with what frequency children recover from what seems to be the most pronounced uræmia.

The duration of scarlatinal nephritis varies greatly according to its severity. In cases which run a favorable course, the urine is generally abnormal for two to four weeks, or even longer. Death may be due either to uræmia or to dyspnoea. The latter cause is the more frequent one, and may depend upon the ascites and hydrothorax, or upon pneumonia (*vide infra*). Sometimes death comes from cardiac failure, which may now and then be very suddenly developed. The nephritis may go on into chronic renal disease, but this is rare.

Pathologically, the kidneys present, in a more or less pronounced degree, the lesions of ordinary acute hæmorrhagic nephritis (*vide infra*). It is sometimes astonishing to see how apparently insignificant the lesions are, in spite of the grave clinical symptoms. In such cases there is usually a so-called glomerulonephritis (Klebs), in which the lesions are chiefly confined to the walls of the capillaries and to the epithelium of the glomeruli. If the nephritis has been of some weeks' duration, we generally find that well-marked hypertrophy of the left ventricle has already developed, as was first pointed out by Friedländer. We have ourselves observed it, and have even been able to demonstrate it repeatedly during life.

6. *Joints*.—When desquamation begins, or even earlier, pain and swelling may attack a certain number of the joints. This trouble was formerly called scarlatinal rheumatism, but now is usually known as scarlatinal synovitis. It is generally mild and quite temporary. The articular inflammation may, however, be severe and even purulent. This is usually a part of a general pyæmia, as evinced by such other lesions as empyema and subcutaneous abscesses; and they all seem to be caused by the above-mentioned "chain-forming" micrococcus, which swarms in the pus found in all the affected parts.

We have seen a few instances of excessive pain in the muscles of the thighs, accompanied by a moderate, diffuse swelling.

7. Another important complication of scarlet fever is pneumonia. In severe cases lobular pneumonia sometimes appears as early as the first stage of the disease; but it occurs more frequently in connection with the nephritis. The respiration may be very seriously interfered with by it. Inflammations of serous membranes in the chest—viz., endocarditis, pericarditis, and pleurisy—are more rare. They may or may not be accompanied by disturbances in the joints (*vide supra*). Quite severe intestinal symptoms, such as diarrhoea, may appear. These are generally the result of a catarrhal inflammation of the intestinal follicles. Dysentery is less frequent. The enlargement of the spleen has been already mentioned. The liver is also sometimes found to be considerably enlarged.

**Variations in the Course of the Disease.**—The diversities of the clinical picture in different cases of scarlatina will be understood when we consider the variety and number of the disturbances thus far cited. It is to be added that the general course of the disease may exhibit numerous peculiarities, of which it is hardly possible to give an exhaustive presentation. We will content ourselves with a cursory statement of the most important deviations from the typical course.

1. *Rudimentary Forms*.—To this class, in which the disease does not reach a perfect development, belong first the cases of simple sore throat with no eruption, or at most an extremely faint and partial one (*scarlatina sine exanthemate*). Sometimes even the sore throat is hardly to be seen, and there is nothing but a brief and slight fever with mild symptoms of general disturbance. The recognition of these cases as scarlatinal is possible only when we consider their ætiological relation to other undoubted cases of scarlet fever. We had an excellent opportunity to observe them when the disease broke out in the children's wards of the hospital at Leipsic. The diagnosis is sometimes confirmed by a slight though evident desquamation, affecting the hands, feet, legs, and back, or by an acute nephritis, which may follow the mildest attacks of this sort. Many cases of acute nephritis, though apparently wholly spontaneous and primary, must be regarded as ætiologically scarlatinal.

2. *Rudimentary but Pernicious Forms*.—Under this head belong those attacks of scarlet fever where the eruption is scanty or absent, while from the very start the most violent general symptoms appear. There is a very high fever, enormously

maxillary lymph-glands. The neighboring connective tissue will then often present diffuse infiltration and œdematous swelling. This swelling may in severe cases involve the floor of the mouth and the entire neighborhood of the throat. The severity of the trouble in the throat does not always correspond to that in the lymph-glands. Very frequently the swelling of the lymph-glands and the neighboring structures ends in the formation of abscesses.

The croupous and diphtheritic inflammations of the throat are the most important and justly the most feared. We believe that it is a mistake to speak of a "complication of scarlatina with diphtheria." The diphtheria of scarlet fever has, from an ætiological point of view, no relation to the common genuine diphtheria. It is a throat trouble having a direct connection with the scarlatinal process as such. It can, indeed, from its outward appearance,\* be distinguished with difficulty, if at all, from the primary, genuine variety (*q. v.*); and therefore, from an anatomical point of view, it must be termed a croupous or diphtheritic inflammation.

Scarlatinal diphtheria may be united with any of the above varieties of angina, either appearing at the very beginning of the illness, especially in very severe cases, or not till later, at the end of the first or even in the beginning of the second week. It is almost always the sign of a severe attack, and is therefore generally associated with high fever and grave general symptoms. The secondary swelling of the cervical lymphatic glands and the surrounding connective tissue generally attains a severe grade, and it is often very painful. Here, as in the other varieties of severe angina, there is almost always a simultaneous, intense stomatitis, and frequently a purulent coryza. There are often superficial ulcers on the *alæ nasi* and at the corners of the mouth. This form of diphtheria has one peculiarity of great interest and clinical importance. Unlike primary diphtheria, it seldom extends to the larynx, so that it is only in rare cases of scarlet fever that there are symptoms of laryngeal croup. A further important clinical difference between these two forms of diphtheria is that in scarlet fever there is scarcely ever any subsequent paralysis of the soft palate or of the muscles of the eye. A dangerous, but fortunately a rare, complication is œdema of the glottis. This may quickly cause death from suffocation. We may finally mention that puerperal scarlatina is said to have in many cases extremely slight throat complications, or none whatever.

3. We proceed by a natural sequence to the consideration of the affections of certain parts adjacent to the throat, troubles which must be regarded as chiefly the result of direct extension, or of a conveyance of the inflammatory process from the throat.

The stomatitis we have already mentioned, as well as the disturbance in the neighboring lymph-glands† and the surrounding tissue. Parotitis is not rare in severe cases. Of especial importance is the scarlatinal inflammation of the middle ear, which often results in permanent deafness.

This inflammation usually arises at the time of desquamation, but it may occur earlier. It is either a simple catarrh of the middle ear, or, in severe cases, an actual diphtheritic process. The deafness and earache are easily overlooked, as the other symptoms of the patient occupy the attention, so that the ear trouble is first recognized by the occurrence of perforation of the tympanum and subsequent purulent otorrhœa. After this declines there very often remains behind, as we

\* In microscopic preparations, however, according to Heubner's investigations, there are evident differences between genuine primary diphtheria and that of scarlet fever.

† It should be remarked that not infrequently there is also in scarlet fever a slight universal swelling of the lymph-glands (back of the neck, axilla, groins, etc.).

have said, permanent deafness. Statistics have shown that four or five per cent. of all cases of deafness are referable to an attack of scarlet fever in childhood. The otitis is seldom immediately dangerous, but yet cases of purulent meningitis have been observed to follow it.

We have already spoken of the purulent or even diphtheritic rhinitis which almost always accompanies the scarlatinal sore throat. In rare cases there may also occur a purulent conjunctivitis, which is most probably the result of a direct conveyance of inflammatory secretions.

The tongue in scarlet fever deserves special mention. The first coating cleans off, and then the tongue usually presents a very characteristic appearance. It is diffusely reddened and covered with little elevations corresponding to swollen papillæ (strawberry tongue, scarlatinal tongue).

4. The characteristic eruption, as developed in the great majority of cases, has been described above. It remains to describe certain variations from the usual appearances.

First, the eruption may be rudimentary. It is then not pronounced, and visible only on a limited portion of the body (face, trunk, or extremities).

Variations from the type are not rare; sometimes the papules are more strongly developed (*scarlatina papulosa*); very frequently there are little vesicles (*scarlatina miliaris*). This latter form of the eruption appears by preference upon the trunk, but it also may come upon the extremities, and is often brought out by excessive perspiration, or by wrapping up the patient too warmly. Many epidemics are noticeable from the frequent appearance of this miliary form. More rarely the rash has a spotted look, resembling the eruption of measles (*scarlatina variegata*). There may be minute ecchymoses, which are not ominous. Well-developed cases of hæmorrhagic scarlatina are, however, very dangerous, because here the general infection of the system is almost always exceedingly severe; and there is besides, as a rule, a general hæmorrhagic diathesis. Other cutaneous lesions, especially herpes and urticaria, are not so very unusual in connection with the scarlatinal eruption. Furunculosis has been repeatedly observed after the rash fades.

Desquamation generally begins as soon as the rash has completely disappeared, but may not occur till a few days or even one or two weeks later. Its extent corresponds in general to the severity of the eruption, although extensive desquamation may follow a rudimentary eruption. It is seldom bran-like or furfuraceous, as in measles. The rule is for it to be in lamellæ, so that, as we have stated, quite large strips of epidermis may be detached entire.

In rare cases an œdema of the skin appears after scarlet fever, which can not be shown to depend upon nephritis (*vide infra*), but may perhaps be due to an abnormal permeability of the walls of the cutaneous blood-vessels following the eruption (*hydrops scarlatinosus sine nephritide*).

*Kidneys.*—Next to the severer forms of throat trouble, the most important and dangerous complications are located in the kidneys. They may appear as early as the acme of the disease, as in many other infectious diseases. The urine has a trace of albumen. In rare cases the amount of albumen may be considerable. The appearance of the urine is generally not much changed, and the microscope reveals but few abnormal constituents. There are some white and red blood-globules, a few hyaline casts, sometimes one or two renal epithelial cells. This initial albuminuria very rarely gives cause for alarm.

The genuine scarlatinal nephritis scarcely ever develops much before the end of the second or the beginning of the third week. Sometimes it comes even later. In one case under our own observation it did not begin till the thirty-third day of the disease. It may therefore be regarded to a certain degree as a localized re-

lapse. It may be so mild as to cause no subjective symptoms whatever, and would be unnoticed if the urine were not carefully examined. On the other hand, it may be accompanied by the gravest symptoms, and soon terminate fatally. It may follow either severe cases or the mildest, so that the rule should be to examine the urine in every case of convalescence from scarlet fever as often and as accurately as possible. No exact statement can be made as to the frequency of this complication, for it is much more common in some epidemics than in others.

The development of nephritis is often marked by a fresh rise of temperature. The elevation may be slight or it may reach  $104^{\circ}$  ( $40^{\circ}$  C.). According to our own experience, the fever often comes a day or two earlier than the changes in the urine. As the nephritis goes on, it is very often accompanied by a moderate fever with remissions. This fever may be almost wholly absent, especially in mild cases. The pulse generally becomes harder, and is sometimes quickened; but in many cases it will be slow, and it is sometimes irregular. Among other objective symptoms, the first to excite notice is generally a slight puffiness of the face, which is usually pale. The eyelids, particularly, present an evident œdema. In the milder cases this œdema remains limited, while in others it gradually increases in extent and degree, involving first, as a rule, the dependent parts of the trunk, and later the extremities. Severe cases develop a pronounced anasarca. There are then, usually, effusions into the serous cavities, especially ascites and hydrothorax. The hydrothorax is frequently combined with severe bronchitis, and then may occasion extreme dyspnoea.

The urine exhibits the most important changes. These may be insignificant in the milder cases, but are very pronounced in the severe ones. The amount is much diminished. Sometimes there will be for several days almost complete anuria. In cases of any severity the urine is turbid, dark, often evidently bloody, with increased specific gravity (about 1015 to 1025), and containing a large amount of albumen. The sediment is generally abundant, and exhibits numerous hyaline casts of various lengths and diameters. To these may be attached red or white blood-corpuscles, detritus, granules of hæmatoidin, or bacteria. In cases of some duration the casts are often moderately fatty. Very frequently there are found noticeably long and broad waxy casts, which are opaque and yellow. In many cases of scarlatinal nephritis the urine is peculiar in having very many white blood-corpuscles, either isolated or adhering to the casts. These undoubtedly originate for the most part in the kidneys. Red globules, some of them in the form of colorless rings, are found. They are usually present in small numbers, but may become more abundant, especially for a day at a time. Renal epithelium is frequently seen, but not invariably nor in very large amount. It must be mentioned, in conclusion, that in some rare instances the autopsy discloses quite a marked nephritis, although the urine was apparently normal during life, or at least was not very abnormal.

Uræmic symptoms are not infrequent. They may be of all degrees of severity. They will be described in detail under diseases of the kidney (*vide infra*). The uræmia may be so severe as to cause convulsions, coma, and death; but it is remarkable with what frequency children recover from what seems to be the most pronounced uræmia.

The duration of scarlatinal nephritis varies greatly according to its severity. In cases which run a favorable course, the urine is generally abnormal for two to four weeks, or even longer. Death may be due either to uræmia or to dyspnoea. The latter cause is the more frequent one, and may depend upon the ascites and hydrothorax, or upon pneumonia (*vide infra*). Sometimes death comes from cardiac failure, which may now and then be very suddenly developed. The nephritis may go on into chronic renal disease, but this is rare.

Pathologically, the kidneys present, in a more or less pronounced degree, the lesions of ordinary acute hæmorrhagic nephritis (*vide infra*). It is sometimes astonishing to see how apparently insignificant the lesions are, in spite of the grave clinical symptoms. In such cases there is usually a so-called glomerulonephritis (Klebs), in which the lesions are chiefly confined to the walls of the capillaries and to the epithelium of the glomeruli. If the nephritis has been of some weeks' duration, we generally find that well-marked hypertrophy of the left ventricle has already developed, as was first pointed out by Friedländer. We have ourselves observed it, and have even been able to demonstrate it repeatedly during life.

6. *Joints*.—When desquamation begins, or even earlier, pain and swelling may attack a certain number of the joints. This trouble was formerly called scarlatinal rheumatism, but now is usually known as scarlatinal synovitis. It is generally mild and quite temporary. The articular inflammation may, however, be severe and even purulent. This is usually a part of a general pyæmia, as evinced by such other lesions as empyema and subcutaneous abscesses; and they all seem to be caused by the above-mentioned "chain-forming" micrococcus, which swarms in the pus found in all the affected parts.

We have seen a few instances of excessive pain in the muscles of the thighs, accompanied by a moderate, diffuse swelling.

7. Another important complication of scarlet fever is pneumonia. In severe cases lobular pneumonia sometimes appears as early as the first stage of the disease; but it occurs more frequently in connection with the nephritis. The respiration may be very seriously interfered with by it. Inflammations of serous membranes in the chest—viz., endocarditis, pericarditis, and pleurisy—are more rare. They may or may not be accompanied by disturbances in the joints (*vide supra*). Quite severe intestinal symptoms, such as diarrhoea, may appear. These are generally the result of a catarrhal inflammation of the intestinal follicles. Dysentery is less frequent. The enlargement of the spleen has been already mentioned. The liver is also sometimes found to be considerably enlarged.

**Variations in the Course of the Disease.**—The diversities of the clinical picture in different cases of scarlatina will be understood when we consider the variety and number of the disturbances thus far cited. It is to be added that the general course of the disease may exhibit numerous peculiarities, of which it is hardly possible to give an exhaustive presentation. We will content ourselves with a cursory statement of the most important deviations from the typical course.

1. *Rudimentary Forms*.—To this class, in which the disease does not reach a perfect development, belong first the cases of simple sore throat with no eruption, or at most an extremely faint and partial one (*scarlatina sine exanthemate*). Sometimes even the sore throat is hardly to be seen, and there is nothing but a brief and slight fever with mild symptoms of general disturbance. The recognition of these cases as scarlatinal is possible only when we consider their ætiological relation to other undoubted cases of scarlet fever. We had an excellent opportunity to observe them when the disease broke out in the children's wards of the hospital at Leipsic. The diagnosis is sometimes confirmed by a slight though evident desquamation, affecting the hands, feet, legs, and back, or by an acute nephritis, which may follow the mildest attacks of this sort. Many cases of acute nephritis, though apparently wholly spontaneous and primary, must be regarded as ætiologically scarlatinal.

2. *Rudimentary but Pernicious Forms*.—Under this head belong those attacks of scarlet fever where the eruption is scanty or absent, while from the very start the most violent general symptoms appear. There is a very high fever, enormously

rapid pulse, and delirium. Such cases must be the result of an uncommonly severe general infection. They usually end in speedy death. Other cases, ending fatally in a few days, have a well-developed rash without other localized disturbances.

3. *Severe Forms with a more Protracted Course.*—In these cases the long duration is not the exclusive result of especial complications, but is likewise due to the severity of the intoxication. One variety is the so-called typhoid form of scarlatina, with persistent high fever and severe constitutional symptoms. Another variety is the hæmorrhagic form briefly mentioned above, in which there are extensive hæmorrhages into the skin and into the mucous and serous membranes. This form may run an extremely acute course. Further, in all pernicious forms, there may be severe local complications, particularly diphtheritic or gangrenous sore throat, inflammations of serous membranes, etc. Attacks of this sort are often not produced by the poison of scarlet fever alone, but by secondary complicating processes. While speaking of scarlatinal diphtheria it has already been pointed out that secondary infection of the body may result, principally originating from the diseased throat, and occasioning sometimes a grave septic condition of the whole body, sometimes local disease of distinct parts.

4. In extremely rare cases relapses do occur. After the first illness a fresh eruption breaks out with all the other symptoms of scarlet fever. In anomalous cases, running a severe course, there is sometimes, at an advanced stage, a fresh, imperfect eruption (generally in spots), which Thomas has termed a pseudo-relapse.

**Diagnosis.**—The diagnosis of scarlet fever is made in most cases from the characteristic eruption taken in connection with the other symptoms. We should, however, bear in mind that exceptionally other eruptions appear which exhibit the closest resemblance to that of scarlet fever. 1. After the use of certain drugs, especially atropine (belladonna), quinine, antipyrine, morphine, chloral; and likewise after the ingestion of crabs, fish, etc. 2. As a symptom of other infectious diseases, such as typhoid fever, small-pox; and, above all, in septic diseases (*vide infra*). In an anomalous case factors of importance for diagnosis are the ætiology and the occurrence of desquamation or of a secondary nephritis.

The **prognosis** must in every case be guarded. From what has been said of the course of the disease, it is evident that, even in cases which are at first apparently the most favorable, dangerous complications may appear later, particularly nephritis.

**Treatment.**—The majority of those cases of scarlet fever which take a typical course will recover completely without our aid. In these the task of the physician, so far as treatment is concerned, consists in arranging the details of hygiene and the general care of the patient. The sick-room should be cool, and the diet rather strict, consisting mainly of milk. Broths and eggs may also be allowed. We should see that the skin and the mouth are kept clean. To change the linen frequently, if done with proper precaution, is not only permissible, but very desirable. The favorite practice of rubbing the skin with fat pork has some merit, and is especially to be recommended if the skin be harsh and dry after the eruption has faded.

[From the moment that the disease is declared the patient should be thoroughly anointed daily with carbolized vaseline, lard, or the like; and this should be kept up until desquamation has ceased. Not only is the comfort of the patient promoted, but the danger of the spread of the infection is thereby greatly lessened.]

The scarlatinal disease of the throat must be treated with the greatest attention, the main duty of the physician in this regard being to prevent, if possible, the ingress of the above-mentioned secondary infection. It is therefore our opinion that in every case of scarlet fever the greatest pains should be taken from the very commencement of the disease to maintain complete disinfection of the mouth

and throat. Larger children may use a gargle (two-per-cent. solution of chlorate of potash, one- or two-per-cent. solution of carbolic acid). Inhalation of carbolic-acid spray is also to be recommended where practicable. If there is prostration, or if the child be young or willful, we must cleanse the mouth and throat at short intervals, by means of a spray-apparatus, with disinfectants, such as carbolic acid or permanganate of potash in solution. Sometimes it is a good plan to let the patient swallow slowly a half-teaspoonful of a solution of potassic chlorate (about 1 to 40) every half-hour or oftener, with the object of contributing to the local disinfection of the throat. If scarlatinal diphtheria nevertheless develops and the cervical lymph-glands begin to increase further in size, there is reason to hope, according to the experience of Taube and Heubner, that parenchymatous injections into the tissue of the tonsils or the palatine arches may yet check the spread of the secondary infection. About 6 minims (a Pravaz syringe half full) of a three-per-cent. solution of carbolic acid may be injected twice daily upon each side by means of a long hollow needle and a subcutaneous syringe.

If the nose be likewise affected, the chief thing to do is frequent cleansing and syringing while the head is bent forward. We should be on the watch for the possible occurrence of otitis. In this particular the physician is often guilty of sins of omission. Much harm may be averted by a prompt cleansing of the ears, or, if need be, by insufflation of air into the middle ear, or paracentesis of the membrana tympani.

Inflammation of the glands in the neck, if severe, is prone to pass on to suppuration, and must then be treated surgically. When the swelling has just begun, or is still moderate, we may try to cure it by rubbing in iodoform ointment (1 to 15) two or three times a day. Ice is generally not so well borne as warm applications (poultices or warm bran-cushions).

If there be continuous high fever, accompanied by rather severe constitutional symptoms, a moderate employment of the cold-water treatment is strongly to be recommended. The baths seldom need to be cooler than 81° to 88° (22°-25° R.), and are to be employed two or three times daily, or oftener in severe cases. If the nervous disturbance be serious, or if the respiration be impaired, the patient should be douched with cold water during the bath. At the same time wine or strong coffee is to be given as a stimulant, or, if cardiac failure and signs of collapse appear, the best remedy is subcutaneous injections of camphor. We are convinced that internal antipyretics, such as antipyrine, may usually be dispensed with, although in private practice we may be obliged to employ them.

If the pulse is abnormally rapid, and there is danger of cardiac failure, we can employ, besides stimulants, an ice-bag placed over the heart. Digitalis may also be tried cautiously.

The scarlatinal inflammation of the joints is sometimes improved by salicylate of soda (forty-five to sixty grains, grm. 3 to 4, in one dose [!]). Sometimes, however, this remedy has failed us.

We know of no means to avert the nephritis. In justice to himself, the physician must always at the start point out the possibility of its occurrence, and must avoid as far as possible errors in diet or exposure to cold on the part of his patient. He may thus escape blame. For the treatment of the nephritis and its results, see the section on renal diseases. We must likewise refer the reader to the appropriate chapters for the treatment of other possible complications of scarlet fever.

The patient must, as a rule, keep his bed three or four weeks, even if convalescence be uninterrupted.

[This injunction is rather extreme. Nephritis is as likely to follow a mild as a severe case, and occurs sometimes in spite of every precaution. The physician

should use his discretion as to the length of time the patient is kept in bed, carefully guarding against exposure to cold and imprudence in diet.]

The disease is so dangerous that, whenever a case occurs in a family, isolation is absolutely demanded, and, if possible, all the other children should be sent away. If this advice be disregarded, we can reject all responsibility for any further cases and their results.

[Scarlet fever is a disease at once so highly contagious and so common that it may be taken as the type of its class. Its hygienic treatment and the measures needful to prevent its spread consequently deserve more minute detail.

The sick room should be at the top of the house, if possible, and exposed to the south; every unnecessary article of furniture and all ornaments should be removed beforehand, carpets, curtains, and stuffed or upholstered furniture being included. A window should be kept open constantly, top and bottom; in cool weather a fire should be burning; in warm weather ventilation is furthered by placing a gas-burner or large kerosene lamp near the throat of the chimney. Outside the door of the sick-room a sheet moistened with a disinfectant solution should be carefully hung. Only those whose presence is absolutely necessary are to be allowed in the sick-room, and the physician, when his visit is completed, should pass directly out of the house.

A convalescent should be kept away from all who are liable to contract or convey the disease until desquamation has entirely ceased. Several warm soap-baths should be given before the child emerges into every-day life, and it should finally be dressed in uncontaminated clothing.

For further directions as to the disinfection of the room, the clothing, and the excreta, see pages 26, 27.]

## CHAPTER V.

### MEASLES.

(*Morbilli*.)

**Ætiology.**—In contrast with the malignancy of scarlet fever is the comparatively benign nature of measles, a disease of childhood which is but little feared even by mothers. It is so wide-spread, and the susceptibility to it is so universal, that measles passes for an almost unavoidable but comparatively insignificant annoyance. Indeed, few escape it; and probably the reason that adults have measles so much less frequently than children is simply that most adults have already suffered from it in childhood. A second attack of measles in the same individual may occur, but it is certainly extremely rare.

[In highly civilized countries measles has prevailed so long that it would seem that a relative resistance against the poison has been acquired. The frightful ravages of the disease when it was planted in virgin soil, as among the Fiji Islanders not many years ago, apparently bear out this view. The susceptibility to measles is greater and more widespread than is that to scarlet fever—that is to say, fewer individuals reach adult life without having experienced an attack of the former than of the latter.]

Measles generally comes in epidemics. Sporadic cases are exceptional. In this respect measles differs decidedly from scarlet fever. The rapid spread of the disease when it has once broken out is a result of its great contagiousness. If one child in a family is attacked, the others almost always take the disease. The infection may be transferred even by well people and by means of articles with which the sick have come in contact. We are not yet acquainted with the spe-

cific poison of measles, although its existence is to be taken for granted, nor with the details of its transmission. Still it seems most probable that the poison is inhaled through the mouth and nose, and that this is the reason why its effects are usually first developed in the respiratory passages (*vide infra*). The disease can be artificially produced by inoculation of healthy children with the blood or liquid secretions of those suffering from it.

**Clinical History.**—The length of the stage of incubation is tolerably uniform. It is ten days to the beginning of the first symptoms, and thirteen or fourteen days to the breaking out of the eruption. These figures have been established by the observations of Panum, the opportunity having been afforded upon the first introduction of the disease into the Faroe Islands. As a rule, there are no especial prodromata during the period of incubation except some slight elevations of temperature. At the end of ten days the initial stage\* begins, generally suddenly, and with an abrupt rise of temperature to 102° or 104° (39°–40° C.). At the same time the characteristic catarrhal symptoms appear: nasal catarrh (coryza), to be recognized by the abundant nasal secretion, the frequent sneezing, sometimes also by nose-bleed; more or less severe conjunctivitis, recognizable by the photophobia, the reddening of the eyes, and the increased flow of tears; and, lastly, symptoms of a catarrh of the upper part of the respiratory tract, usually moderate, but nevertheless causing hoarseness and a slight cough. With all this the general condition is disturbed, the children are restless, have headache, and eat little. Symptoms of a mild sore throat are not infrequent, but are very far from being so prominent as in scarlet fever.

These initial symptoms last, as we have said, three or four days. Then the eruption begins (stage of eruption). This is very often preceded for a day or two by a peculiar, usually spotted, reddening of the hard and soft palates, termed "eruption upon the mucous membrane." The true eruption of measles begins almost always in the face, on the cheeks, forehead, and around the mouth (contrasting with the characteristic pallor of the chin in scarlet fever), and spreads from there rapidly downward over all the rest of the body. The eruption consists at first of little papillæ, corresponding to the follicles. These are soon surrounded by a pale-red, slightly elevated border, and in many cases become confluent. Perfectly flat elevations, of various sizes and of extremely irregular, dentated, roundish, or angular shape, develop. These are often so thickly crowded together as to touch one another, but usually limited portions of normal skin intervene between them. Within each raised spot the little follicular papillæ remain visible.

With the beginning of the eruption the fever rises, having been, as a rule, slight during the last days of the initial stage. It attains about 104° or 105° (40°–40.5° C.). In thirty-six to forty-eight hours the eruption reaches its full development and its greatest extent. The fever and the catarrhal symptoms also persist for the same length of time. Sometimes we find a slight swelling of all the lymph-glands. Then follows a decline of the fever, usually rapid, and indeed almost by crisis, while the eruption after a short period of full development begins gradually to fade during the two or three days following. At the same time the catarrhal symptoms diminish. A more or less extensive desquamation of the epidermis begins, scarcely ever in large pieces as in scarlet fever, but in little scales, "like bran." After eight or ten days, if the disease runs a normal course, the patient is fully convalescent.

---

\* We consider the term "initial stage" more correct than "prodromal stage." The "prodromal symptoms" are the first slight symptoms which occur during the time of incubation of an infectious disease, while the symptoms presented by measles before the breaking out of the eruption are a part of the already developed disease.

After this brief description of the usual course, we must consider more closely some of the symptoms and possible complications.

The fever (see Fig. 6) of measles exhibits, as has been already implied, a tolerably typical course. It begins with a rather marked and rapid rise upon the commencement of the disease. On the morning of the second day there is usually a marked remission, often to normal. In the last two days of the initial stage the fever is moderate, very rarely being so high as at the beginning. With the eruption there is a new, rapid rise, usually higher than the initial one, so that we may well divide the fever into two periods—the prodromal fever and the eruptive fever. This latter is but brief and does not persist, as in scarlet fever, during the entire duration of the eruption. It falls by crisis when the rash has attained full development. There may, to be sure, be slight elevations of temperature during the next day or two; but, if the fever is considerable and persistent, it is always a sign that complications have arisen, probably in the respiratory apparatus.

FIG. 6.—Example of the temperature curve in measles.

The eruption usually assumes the form described above, but may present manifold varieties. Sometimes its development is rudimentary. Sometimes it does not begin in the face, but on some other part of the body. This is generally regarded as a sign that the case will be anomalous in other ways as well. The individual spots may be smaller than usual, and may remain entirely separate from each other (*morbilli papulosi*). In other cases the eruption is so confluent (*morbilli confluentes*) that it resembles the eruption of scarlatina. The formation of vesicles (*morbilli vesiculosi*) also occurs, but much more rarely than in scarlet fever. Haemorrhagic measles are also observed, but usually only in the form of small, capillary bleeding, and in cases that otherwise run a perfectly favorable

course. Very rare cases have indeed been described, with a general haemorrhagic diathesis and bad symptoms, resembling haemorrhagic scarlatina. It is doubtful whether the "black measles" of the old writers was actually measles at all. In addition to the proper eruption of measles, other eruptions sometimes develop—among others, vesicles, wheals, and pustules.

The complications of measles are for the most part exaggerations, or abnormal varieties and extensions, of those troubles which are observed during the usual mild course of the fever. As in scarlet fever (*vide supra*), we often have to deal with the effects not of the original, but of secondary infection. Compared with the great majority of mild attacks taking the typical course, cases presenting complications of any severity are rare, and much less frequent than in scarlet fever. Epidemics are only now and then distinguished by unusual severity.

Often quite grave eye diseases are developed, particularly blennorrhagic conjunctivitis, keratitis, and iritis.

Marked inflammation of the mucous membrane of the nose, throat, and larynx may prolong the course of the disease. These are often merely exaggerations of the usual catarrh. Otitis media likewise sometimes occurs. A laryngitis of marked intensity, with considerable swelling of the parts involved, may pro-

duce much discomfort, or even symptoms of stenosis ("false croup"). Actual croupous and diphtheritic lesions of the throat and larynx also occur (diphtheria of measles). This last is indeed much rarer than scarlatinal diphtheria, but may have the same unhappy termination. It is worth mentioning that sometimes genuine laryngeal croup is observed in measles, unaccompanied by lesions of the pharynx.

It is, however, in the lungs that the most frequent and important of all complications in measles occur. The usual mild bronchitis becomes very intense, extends into the bronchioles (capillary bronchitis), and then results, for the most part, in a more or less extensive, lobular, catarrhal pneumonia (*q. v.*). This is almost always to be suspected when moist râles are heard in abundance over a large part of the chest, and when there is at the same time persistent fever and pronounced difficulty in respiration, with cough or dyspnoea. We get decided dullness on percussion only when the separate centers of infiltration are more than usually confluent. Genuine lobar, croupous pneumonia appears much less often than the lobular variety. It attacks one lobe, or several, is attended by high fever, and may end with a well-marked crisis.

The foregoing pulmonary symptoms usually appear at the height of the disease, and persist after the eruption fades. They may delay convalescence for weeks. In other cases measles will seem at the start to run a normal course, the temperature will have already fallen, and then come new fever and the appearance of decided pulmonary disturbance. This is always to be regarded as a grave complication; and especially in feeble children it may lead to death, with the symptoms of impaired respiration, or of constitutional exhaustion.

Marked intestinal symptoms sometimes appear, particularly an excessive diarrhoea, due to intestinal catarrh. It is characteristic of measles that in severe cases such a diarrhoea may assume a pronounced dysenteric character, indicated by blood and slime in the dejections, symptoms which usually depend upon the development of follicular colitis with ulcerations.

Now and then still other complications may present themselves, of which a full enumeration is impossible. Nephritis does occur, but far less often than in scarlet fever. A simple albuminuria during the acme of the disease is not infrequent, but as a rule has no especial clinical significance. We should mention gangrene of the cheek, the so-called noma, as a complication, which is very rare but apparently characteristic.

**Peculiarities in the course of the disease** are much rarer in measles than in scarlet fever. Yet we see, on the one hand, unusually mild or rudimentary cases, in which either the rash or the other local symptoms are remarkably slight, and on the other hand, abnormally severe cases. These latter are distinguished by the unusual height or persistence of the fever, by the severe constitutional and nervous symptoms, and further by the early appearance of complications. Such cases have been termed "typhoid measles." We have already mentioned the severe form of hæmorrhagic measles.

We should notice the clinical relation which measles bears to some other infectious diseases—to whooping-cough and tuberculosis. Measles and pertussis (*q. v.*) may follow each other in the same individual at a short interval, sometimes one and sometimes the other taking the initiative; epidemics of the two diseases prevail with comparative frequency at the same time. Tuberculosis is likewise to be mentioned as an important sequela of measles. Its frequent appearance at the close of measles is of course to be explained by supposing either that, in children who are already the victims of tubercle, the further extension of the tuberculosis is favored by measles, or that the catarrhal inflammation due to measles leaves behind it an especial predisposition to infection with the tubercular poison.

The **diagnosis** of measles, as of the other acute exanthematous diseases, is based chiefly upon the eruption. Personal experience does more to sharpen the perception than can the fullest descriptions. We can merely suspect the disease during the initial stage unless an epidemic prevails. If, beside the characteristic catarrhal symptoms, the above-mentioned eruption on the mucous membrane of the palate exists, the diagnosis becomes tolerably certain. We should consider that eruptions similar to that of measles appear in other diseases, more especially in röteln, scarlet fever, typhus fever, in the beginning of small-pox, and in syphilis. Furthermore, we need to exclude eruptions due to such drugs as antipyrine, turpentine, and balsam of copaiba. In doubtful cases we shall be enabled to form a decided opinion by the other symptoms, and, above all, by the further course of the disease.

**Prognosis.**—We have already remarked how favorable in general the prognosis is, but we must here repeat that all epidemics do not exhibit the same benign character, and that in every case the physician must bear in mind the possibility of complications, and particularly the danger of severe pulmonary disturbances.

**Treatment.**—The patient should in general be kept somewhat warmer than in scarlet fever. Even in what seem to be the mildest cases the child should be kept in bed till desquamation is over. The sick-chamber is to be somewhat darkened, on account of the photophobia which usually exists at first. In this way, normal cases run on favorably without any especial therapeutic interposition. The catarrhal symptoms, however, should always be heeded, since to disregard them may lead to their becoming aggravated. The chief requisite is cleanliness. At regular intervals the eyes, the nasal cavity, and the mouth should be washed out with lukewarm water.

If, despite all this, certain disturbances appear in a worse form than usual, or if complications develop, these must receive especial attention. Severe eye troubles should be treated according to the usual ophthalmological practice; and here unguentum hydrargyri oxidi flavi (1 to 100) [U. S. P. is 40 to 420] and atropine are chiefly employed. The treatment of croupous trouble in the throat or larynx will be fully described in a later chapter. For the pulmonary troubles, lukewarm baths, combined if need be with rather cool douches, constitute the most effectual remedy, which we should employ if it is in any way possible. We thus evoke deeper inspirations and promote expectoration, and thereby contribute largely to preventing the development, or the aggravation, of severe lung trouble. Inhalations of steam or of medicated fluids are often advantageously combined with the baths. To substitute the cold pack for the baths is in general justifiable only when the baths are not practicable. Still, the pack does good. If employed, it should be kept up for three hours at a time, two or three times a day. The breathing will be improved, and usually the child will go quietly to sleep. We are not acquainted with any internal remedies for the lung troubles which are at all reliable. In rare instances the excessive accumulation of mucus in the bronchi requires the administration of an emetic. As expectorants we may try ipecac, liquor ammonii anisatus, or benzoin. If considerable intestinal disturbance arises, we must employ small doses of opium, or calomel, or subnitrate of bismuth. We hardly need to say that, whatever else is done, the strength of the patient should be kept up as much as possible by giving wine, broths, milk, eggs, etc. For at least two or three weeks after the disease has ended, the child must be very carefully watched.

As the disease is usually so mild, prophylaxis is not very strenuously attempted. If one child in a family is attacked, it is probably already too late to isolate the others, and it is even an advantage to the family to have all the children finish at

W. A. S. S. I. 1911

once what they will hardly be able eventually to avoid. We would make an exception in favor of isolation if the disease prevailed in a severe form.

[It is not customary with us to insist so strongly upon isolation and thorough disinfection as in scarlet fever. But the tendency of the present day is toward a wide application of the principles of preventive medicine. It is certainly of no advantage to a child to contract the measles. Delicate children, especially those with tubercular predisposition, should be carefully guarded against it; and, even if it is decided that it is not worth while to attempt to confine the disease to one member of a family, every precaution should be taken against infecting other families. Under suspicious circumstances, consequently, children are to be kept away from school and from contact with others.

If there is any reason to fear the development of tuberculosis, every possible hygienic means should be employed in order that full vigor may be regained.]

## CHAPTER VI.

### RÖTHELN.

(*German Measles.*)

RÖTHELN is a disease similar to measles, but distinct from it, although formerly often confounded with it, and perhaps with scarlet fever as well. The observations of Steiner, Thomas, and others leave now no room to doubt that these diseases are distinct, for epidemics occur in which all cases present the characteristic peculiarities ascribed to rōtheln. But the best proof is that children who have had rōtheln are not infrequently attacked by genuine measles later. It may indeed be very difficult in an individual case to decide which disease is present; but that rōtheln does exist, as an independent form of disease, can be denied by those alone who have never seen it.

After an incubation of about two or three weeks the disease begins with the appearance of the eruption. Initial symptoms preceding the eruption are either wholly absent or at most last for half a day. The eruption is decidedly like that of measles, but its individual spots are smaller. They are seldom larger than small peas and circular, being only exceptionally as dentated and irregular in outline as are the maculæ of measles. They appear on the whole face, the head, the trunk, and the extremities, are pale red (sometimes deep red), but slightly elevated, and are not apt to become confluent. In rare instances, small vesicles develop upon the macules. The soft palate sometimes exhibits, as in measles, a faint macular eruption at the beginning of the disease. After two to four days the eruption fades. There is usually no decided desquamation.

Other symptoms of disease than this eruption are slight. Fever in many cases appears to be entirely absent. As a rule, there is for a day or two a slight elevation of temperature, reaching 102° (39° C.) at most. Tokens of a moderate catarrh of the conjunctiva, the nasal mucous membrane, the throat, and the larynx are also observed—viz., photophobia, nasal discharge, and cough. Often, the cervical lymph-glands are more or less swollen. The constitutional disturbance is generally so slight that the child can hardly be kept in bed. Important complications hardly ever occur.

The prognosis of rōtheln is therefore perfectly favorable, and the employment of any special treatment is needless.

## CHAPTER VII.

## SMALL-POX.

(Variola, Varioloid.)

**Ætiology.**—Small-pox has been known for centuries, although formerly often confounded with other diseases.\* It is one of the most dreaded acute infectious diseases, and in earlier times it has destroyed thousands in its pestilential progress. It was the discovery of the possibility of prophylactic inoculation, and the ever-increasing spread of this precautionary measure, which first robbed the disease of some portion of its terrors.

Numerous statements have been made about the occurrence of micro-organisms in the variolous eruptions on the skin and mucous membranes, but we are compelled to say that we are not yet acquainted with the specific, organized poison of small-pox, however strongly justified we may be in assuming its existence. Bacteria can in fact easily be demonstrated in the eruption of variola, but most of them come from the surrounding atmosphere, and have no relation to the specific variolous processes. The foci of bacteria found in the internal organs (liver, spleen, kidneys) are also due, as their discoverer, Weigert, himself supposed, to the secondary ingress of other varieties of micro-organisms, and are not directly associated with the variolous process, the diseased condition of the skin furnishing a ready entrance for infectious matter.

Predisposition to variola, except as diminished by vaccination (*vide infra*), is universal. The disease may appear at any age, even *in utero*. Women are believed to be especially liable to it during pregnancy and child-bed. It is said that persons ill with another acute infectious disease, such as scarlet fever, measles, or typhoid fever, are, for the time being, tolerably secure from infection with small-pox; but this rule has exceptions. The same individual rarely takes the disease a second time.

A case of variola is always the result of transmission of the poison to a healthy person from one who is already ill with it. The specific poison certainly is most abundant in the diseased portions of the body and in the pus of the suppurating pocks, as well as the crusts and scales which are left when these have dried up; but the disease is also contagious in its earlier stages, before the pustules develop, and even, according to a few observations, during the stage of incubation. Certainly the variolous poison is very volatile—that is, it is prone to disseminate itself through the air in the neighborhood of the patient. In order to catch the disease it is not necessary to touch the patient, but merely to remain in his vicinity. In many cases we can not, however, determine with exactness the mode of transmission, since the contagion may either be direct or by means of objects and utensils with which a patient has come in contact—for example, the soiled linen. The dead body is capable also of transmitting the disease. In general, numerous instances point to a considerable “tenacity” in the poison. The precise manner of infection is not yet known. It is most probable that the poison is drawn into the lungs with the inspired air.

It has been demonstrated that the disease can be transmitted to healthy persons by direct inoculation of the contents of the variolous pustules. It is stated that monkeys and other animals may be successfully inoculated in the same way. Whether inoculations with the blood of the sick will reproduce the disease is not

\* The very name small-pox (*petite vérole*) is significant of its confusion with syphilis, which was termed the “great pox.”

yet settled. The secretions (saliva, sweat, urine, and milk) do not apparently contain the infectious matter.\*

**Course of the Disease, Variola and Varioloid.**—The stage of incubation lasts some ten to fourteen days, often a somewhat shorter time, seldom longer. During this period prodromal symptoms are absent or insignificant.

The disease itself begins suddenly with what are usually very characteristic initial symptoms—rigor, fever, headache, and intense pain in the loins. It is only in comparatively few cases that one or another of these symptoms is slight or wanting. The constitutional symptoms may be very severe—a dry tongue, stupor, wakefulness, delirium. The fever continues intense for some days. The pulse is much quickened. There is almost total anorexia, and often there is vomiting. There is constipation, or, more rarely, diarrhœa. Frequently there is a slight sore throat, and sometimes a slight bronchitis. The spleen is enlarged in most of the severe cases, and the urine often has a trace of albumen. In women, menstruation occurs in a remarkably large number of cases. The proper variolous eruption does not at once appear, but from the second day other characteristic efflorescences are not rare. These are termed the initial rash of small-pox. We may find either a diffuse or macular erythema, extending in varying degree over the trunk and extremities, or a hæmorrhagic eruption with small spots appearing by preference upon the hypogastrium and the inner surface of the thighs (in the so-called femoral triangle of Simon). It is noteworthy that this particular region is said often to remain free from the proper variolous eruption. The erythema soon vanishes, but the petechiæ remain visible for some time.

The initial stage, just pictured, lasts usually three days. Severe symptoms occurring at this time do not exclude the possibility that the further course of the disease may prove favorable, while mild symptoms are of good omen.

At the end of the third or on the fourth day the temperature makes a decided fall, and the regular variolous eruption begins to be developed upon the skin—the *stadium eruptionis*. During this period an evident difference among the separate cases becomes manifest. This distinction can not indeed be always drawn with a narrow line, but it is noticeable enough to justify the establishment of two types of variolous disease. We refer to the division into a severe form (*variola vera*), and another, mild form (*varioloid*). The *variola* proper has a well-developed eruption with many pustules, and, as a result of this, a second stage of fever (*stadium suppurationis*). *Varioloid* has a much more scanty eruption, and little or no suppurative fever. We must now discuss these two forms separately.

#### VARIOLA VERA.

The eruption almost always begins in the face and upon the hairy scalp, appearing somewhat later on the trunk and arms, and last of all upon the legs. It begins in the form of little red dots and spots, which develop in about two days to small papules (*stadium floritionis*). If the hand be passed over thickly set and well-developed papules of *variola*, a peculiar soft, satin-like feeling is perceived. On the points of these papillæ a little vesicle forms. This keeps growing larger and larger, its contents become turbid and purulent, till at last, on the sixth day of the eruption and the ninth of the disease, the development of the genuine pustule of *variola* is complete (*stadium suppurationis*). The pustule usually presents upon its summit a little dimple ("Pocken-nabel"), and is surrounded by a red border or "halo." Where the pocks are especially close together, as in the face, the skin between them is diffusely swollen, and the consequent burning and pain are excessive. The countenance becomes much disfigured. Often the eyes can not be opened because of the œdema. The hands also are apt to be intensely affected,

especially the back of the hands, and also all parts which have previously been injured in any way (pressure or friction of clothing, etc.). The immunity of the skin in the so-called femoral triangle has been already mentioned.

At the same time with the eruption upon the skin, or even somewhat earlier, a perfectly analogous efflorescence develops upon the mucous membranes. The chief places for its appearance are the mouth and throat, the tongue, the soft palate, the nasal cavity, also the larynx, the trachea, and the upper part of the œsophagus. In the vagina and rectum it is rare and scanty. In this mucous efflorescence, however, there are no proper pustules, but small, superficial ulcers. These result from the maceration of the uppermost layers of the mucous membrane. They sometimes become confluent. The annoyance produced by this eruption in the mouth and throat is, of course, very great. The pocks in the larynx manifest themselves by hoarseness, and occasionally by symptoms of stenosis.

As we have said, the beginning of the eruption is the signal for a noticeable fall in the temperature. But in true variola the fall does not reach the normal, or only temporarily. The other symptoms likewise remit, especially the headache and lumbar pain. When, however, the suppuration begins, the fever rises once more, and there are fresh symptoms of constitutional disturbance. This is the time for the dreaded attacks of delirium, during which the patient must be vigilantly watched, lest some untoward event happen. Now, too, complications may arise (*vide infra*).

On the twelfth or thirteenth day of the disease the pustules begin to dry up (*stadium exsiccationis*). The purulent contents of the pustules, part of which have burst, form yellow crusts, the swelling of the skin subsides, and, a few days later, the crusts and scabs begin to fall off. With the beginning of desiccation, the fever declines; the local as well as the constitutional symptoms become daily slighter, and convalescence follows. The healing of the pustules is frequently accompanied by an extremely troublesome itching. After the scabs have been cast off, the skin presents pigmented spots, which persist for months. Wherever the cutis vera has itself been destroyed by the suppuration, a scar is inevitable. Thus arise the familiar scars of small-pox, which continue visible through life. Very often, after the end of the disease, there is almost complete alopecia. The hair often grows again, but not always.

#### VARIOLOID.

The distinction between varioloid and variola vera is not in kind, but in degree. Varioloid is only a milder form of variola. There is, as we have already said, no sharp boundary-line between the two. Varioloid is most often observed in those whose susceptibility to the variolous poison has been diminished by vaccination (*vide infra*).

As above mentioned, the behavior of the disease during its initial stage will not permit us to decide positively whether variola or varioloid will be developed. It is true that if the symptoms be especially mild, we may guess that it will be varioloid; and, likewise, the appearance of the initial erythema already spoken of is regarded as a favorable omen.

Shortly after the pocks begin to appear, the decision can almost always be made with certainty. In varioloid the eruption is rather scanty. It is often irregular, and does not by any means always begin, like that of variola, in the face, but often on the trunk. The individual pocks are in no way different from those of variola; but it often happens that they do not pass through all the regular stages to full suppuration, but undergo resolution before this occurs. Such cases, where there is nothing beyond papillæ or vesicles, are sometimes spoken of

as *variolois verrucosa seu miliaris*. The scantiness of the eruption and the limited amount of suppuration have for their corollary an absence, or at least a very slight development, of the suppurative fever.

When the eruption appears the temperature usually falls by crisis to the normal level and remains there. The desiccation may begin as early as the eighth or tenth day of the disease, so that the whole duration of varioloid is considerably shorter than that of variola. Grave complications are very exceptional. The pocks may develop upon the mucous membranes, but here, too, they are scanty and not very vigorous.

#### COURSE OF THE FEVER, SYMPTOMS PRESENTED BY SEPARATE ORGANS, AND COMPLICATIONS.

1. *Fever* (vide Fig. 7).—In the initial stage, as we have said, the temperature rises rapidly as a rule, with a pronounced rigor; and during the first days it very often reaches  $104^{\circ}$  to  $106^{\circ}$  ( $40^{\circ}$ – $41^{\circ}$  C.). It sinks on the third to the sixth day, when the first papillae develop, and now, in the case of varioloid, falls rapidly to normal, and remains there. In variola the decline is slower and less complete; and with the beginning of suppuration the temperature begins to rise again. The violence of this suppurative fever is usually in direct proportion to the severity of the eruption. It has manifold fluctuations, but seldom lasts, in severe cases, less

FIG. 7. — Example of the temperature curve in true small pox.

than a week. Temperatures of  $104^{\circ}$  ( $40^{\circ}$  C.) and higher are common. The fever declines by lysis. In case of approaching death, the temperature may be extremely high, even reaching  $108^{\circ}$  or  $109^{\circ}$  ( $42^{\circ}$ – $43^{\circ}$  C.).

2. *Skin*.—We have already described the macroscopic appearance of the eruption. It remains to mention briefly the histological phenomena. The first demonstrable changes are in the cells of the deeper layers of the rete Malpighi. As a result of the variolous infection, the cells perish, are swollen by the lymph which escapes from the papillary blood-vessels, and are transformed into flaky, homogeneous masses without nuclei ("coagulation necrosis" of Weigert). The lymph becomes more and more abundant, and crowds the cells farther and farther apart. These are thereby finally changed into threads and membranes, forming a distinct net-work in the vesicle. This explains why, if such a vesicle be pricked, its entire contents are never discharged at once. Great numbers of white corpuscles escape, along with the lymph, from the blood-vessels, and finally render the contents of the original vesicle purulent. Proliferative processes occur

in the surrounding epithelial cells, which are still intact, and thus the margin of the vesicle becomes elevated, while the dead portion in the center sinks in. Thus the pock becomes umbilicated. If a portion of the papilla itself suppurates, a scar must be left on healing. If the process remains limited to the epithelium, complete regeneration takes place, and the skin reassumes its normal appearance.

Certain secondary complications, which sometimes attack the skin, remain to be mentioned: abscess, phlegmon, erysipelas, gangrene, and bed-sores. None of these are directly due to the specific variolous intoxication.

3. *Respiratory Organs.*—The disturbances here are in part symptoms of the specific process of the disease, and in part secondary. The frequent occurrence of secondary symptoms in small-pox is easy to understand (compare the chapter on lobular pneumonia). Of the primary symptoms, we should mention genuine pocks in the larynx, the trachea, and the larger bronchi. As sequels to these, more or less severe secondary disorders are very frequent: laryngeal ulcerations, which may even lead to laryngeal perichondritis and oedema of the glottis; diffuse bronchitis; lobular pneumonia, often of great extent, due to the inhalation of solid matter into the lungs, and frequently accompanied by pleurisy. It should be especially noticed that lobar, croupous pneumonia is not rare. Whether this be likewise secondary or a direct result of the variolous poison is not yet known.

4. *Digestive System.*—The genuine pocks often develop, as stated, in the mouth and pharynx, and likewise in the upper part of the œsophagus. They are not observed in the mucous membrane of the stomach or intestines. The active diarrhœa sometimes seen depends upon catarrh of the intestine. Dysentery is rare. The eruption in the mouth and throat may result in severe secondary troubles, purulent otitis, parotitis, pharyngeal diphtheria, etc. The spleen is almost always considerably enlarged, and often the liver, but in a less degree.

5. *Circulatory System.*—Pathological changes in the heart are rare, if we except the slight parenchymatous degeneration of its muscular fibers, common to almost all severe infectious diseases. Sometimes there is a slight endocarditis (*q. v.*), which is probably secondary. Pericarditis is rather more frequent.

6. *Organs of Special Sense.*—Genuine variolous pustules occur upon the eyelids and the conjunctiva. Later in the disease there may be keratitis, iritis, or choroiditis.

We have already mentioned the relative frequency of aural disturbances, particularly purulent otitis media.

7. Articular swelling may appear in the suppurative stage. The shoulders and knees are most apt to be attacked. Periostitis also occurs.

8. *Nervous System.*—We find no pathological changes corresponding to the severe nervous derangements manifested during the disease. After the small-pox is over, spinal diseases sometimes occur, with either paralysis or ataxia. Westphal has demonstrated as their cause, in some cases, numerous disseminated centers of inflammation in the spinal cord.

9. Albuminuria is quite frequent in severe attacks, but genuine nephritis is a very rare complication.

**Anomalies in the course of the disease** are manifold. We do not speak of the two typical forms already considered. There are abnormally mild cases, with scarcely any initial symptoms, or with an obscure eruption, or with no eruption at all (*febris variolosa sine exanthemate*). In such cases a correct diagnosis is possible only at the time an epidemic prevails, and by the aid of the attendant ætiological circumstances. There are also abortive cases in which the first symptoms are severe, but which recover with remarkable rapidity.

The abnormally severe cases are more important. First, there is the confluent variety. This is merely the typical process in its completest development. The

initial symptoms are themselves generally very severe, and are followed, without any considerable remission of the fever, by the eruption of hundreds of pustules. The skin of the face and hands is one continuous area of suppuration. The local discomfort is extreme, as is also the intensity of the fever and of the constitutional symptoms. The nervous system suffers most. There is at the same time an unusually abundant eruption upon the mucous membranes. The occurrence of the above-mentioned complications affecting the various organs of the body is frequent. Death is a common result; or, if recovery takes place, it may be delayed by tedious sequelæ.

Hæmorrhagic small-pox is the worst anomalous form. The name is applied to several different varieties. In the first place, any variolous eruption may become more or less hæmorrhagic, and yet the general course of the disease not be essentially altered. Such cases are more common among elderly people, cachectic persons, and drunkards. Secondly, there is a very severe form of small-pox, which is generally quickly fatal. The initial stage is marked by the unusual severity of the symptoms. The abundant eruption soon becomes hæmorrhagic, and there are also ecchymoses in the mucous membranes and the internal organs. This has been called black small-pox, and by Curschmann *variola hæmorrhagica pustulosa*.

There is another form of hæmorrhagic variola, different from these but linked to them by transitional varieties. In it the acute hæmorrhagic diathesis develops during the initial stage. Death almost always occurs before the regular variolous eruption. This most frightful form is usually termed *purpura variolosa*. That it is small-pox is proved by its ætiological relations alone. Otherwise it would be impossible to distinguish it from certain other acute septic disorders. It is prone to attack the youthful and vigorous. Chills, headache, and pain in the loins are the first symptoms, just as in ordinary cases. Cutaneous ecchymoses appear as early as the second or third day. They increase in area so rapidly that one can almost see them grow. They are most extensive in the hypogastric region. There are also ecchymoses in the eyelids, the conjunctiva, the mouth and pharynx, and, as the autopsy discloses, many in the internal viscera. The constitutional symptoms are most severe, and the patient seldom survives the fifth or sixth day of the disease.

**Diagnosis.**—The certainty with which we can make the diagnosis of small-pox in any well-developed case is equalled by the difficulty of deciding about it during the beginning of the disease, or even during the beginning of the eruption. At this period diagnosis may be impossible. When the variolous eruption is in process of development, it may be confounded with typhus fever, with that form of measles in which the papillæ are prominent, with syphilitic eruptions, and with certain forms of erythema exsudativum, just breaking out. We can not here fully discuss all the factors which should be considered in making this diagnosis. It is important not to regard the cutaneous appearances alone, but to note all the other symptoms besides. But it is often necessary to watch a doubtful case for some time before a diagnosis can be established.

**Prognosis.**—The facts which are of greatest weight in prognosis have already been emphasized. We may repeat that during the initial stage the prognosis of any individual case can seldom be determined. If the first symptoms are mild, or if the initial erythema appears, the case is regarded hopefully. The abundance of the eruption has an influence upon the severity of the disease. Circumstances peculiar to the individual are also important—e. g., age, constitution, or alcoholic habits. We have already called attention to the danger of confluent small-pox, and to the almost absolutely fatal prognosis in the genuine hæmorrhagic variety. The mortality varies greatly in different epidemics; on the average it may be taken

at about fifteen to thirty per cent. Beyond doubt, the introduction of vaccination has decidedly lessened the fatality of the disease by diminishing the frequency of the severe forms.

**Treatment.**—1. *Prophylaxis—Vaccination.*—As in all contagious diseases, isolation is of little avail unless complete. This fact has led to the erection in late years of small-pox hospitals. All utensils used by the patient, and his clothing, bedding, and the like, should be most carefully disinfected. The best method is to employ a high degree of heat—viz.,  $240^{\circ}$  to  $250^{\circ}$  ( $115^{\circ}$ – $120^{\circ}$  C.).

These precautionary measures are employed in many other diseases as well, but for small-pox we are acquainted with a peculiar method of prophylaxis. It is founded upon a fact which is at once the most remarkable and inexplicable, and the most beneficent, within the domain of the infectious diseases. We refer to vaccination. It must long ago have been remarked that a person who has had the disease once, enjoys, to a large degree, immunity from any fresh infection. This suggested the idea of exposing children purposely to contagion, so as to insure them from small-pox for the rest of their lives. The actual inoculation of small-pox is said to have been long practiced in India and China. In the year 1717 it was employed by Lady Montague, of England, upon her own son, and with success. Unfortunately, however, the inoculated small-pox proved fatal in many instances; and, being itself contagious, it served to spread the disease still further. Then appeared an article written by the English surgeon, Edward Jenner, in 1798. This informed the medical profession of a fact already known to the rural population of his native place, but which Jenner first established scientifically, and recognized in all its importance. There sometimes occurs a disease similar to small-pox upon the teats and udder of the cow, called *variola vaccina*. It is apparently a local trouble, and can easily be inoculated upon the skin of human beings. Vaccine pustules will be developed upon the spot inoculated. These almost invariably heal without any great constitutional disturbance; but the person vaccinated possesses the same immunity from small-pox as if he had had small-pox itself. This statement of Jenner's was soon confirmed upon every side. The result is the continually spreading custom of prophylactic vaccination. In some countries it is enforced by law, and it can be opposed only by ignorance or by lamentable prejudice.

To explain how vaccination can protect against small-pox in this way is still utterly beyond our powers. We have lately gained this much help in understanding it, that it is no longer an isolated fact; for analogies have been discovered in the case of other acute infectious diseases (cf. the chapters on hydrophobia and malignant pustule). We are likewise in the dark as to the relation between small-pox and vaccinia. Many authors regard the virus of vaccinia as merely a modification of the variolous poison, while others assume that there is a specific difference between the two. As yet, the infectious material of neither has been exhibited in a pure state; and we must for the present therefore leave this question undecided. A statement in support of the essential unity of the two infectious agents can be adduced. The inoculation of cows with small-pox is said to produce vaccinia, which, inoculated in its turn upon children, will result in vaccinia and not in small-pox. This statement rests on doubtful evidence. Careful experiments made in 1865 in Lyons had a different result, showing that the inoculation of cows with the contents of variolous pustules produces an eruption different from that of vaccinia. Children inoculated from these cows had true variola; while no case of small-pox has ever resulted from genuine vaccine lymph.

We can mention only the most important of the details relating to vaccination and the method of its performance. The inoculation is made either with animal

virus, direct from the cow, or with humanized virus, obtained from persons previously vaccinated. The lymph taken from a vaccine-pustule can be kept a long time, either pure or mixed with glycerine, without deteriorating. It is kept in small glass tubes, hermetically sealed, or in a dried form between glass plates which have been thoroughly disinfected and cemented together, [or else upon little "points" made of bone]. The most common mode of vaccination now in use is to make three shallow incisions, 3 or 4 ctm. apart, in the skin of the upper arm, and to introduce the vaccine-lymph into them. The surrounding tissue becomes swollen in three or four days. In seven or eight days the vaccine vesicles are well developed, if the disease takes its normal course. Next they become purulent, and then dry up, and finally, on healing leave the familiar scar behind. The whole process occupies about three weeks. If the vaccination fails, or is but partially successful, it must be repeated after a few months. The protective power of vaccination does not last indefinitely, and therefore re-vaccination is necessary every five or six years. The first vaccination of children usually takes place when they are three or four months old. If they are feeble we wait longer, unless small-pox is prevalent.

It must be confessed that vaccination is not without its dangers. The little cutaneous wound made by it may lead, like any other, to sepsis or to erysipelas. The latter has been called vaccination-erysipelas. But such misfortunes are extremely rare. The "vaccine roseola" deserves especial mention. It appears first upon the arm vaccinated, and spreads over the rest of the body; but it is not a serious matter. It is of course possible that other diseases, among which syphilis is of chief importance, may be inoculated along with vaccinia; but this is a very rare occurrence—much more so than the enemies of vaccination pretend. If the physician exercise proper care in the selection of the person from whom to take humanized virus, it can be entirely avoided. The exclusive employment of animal virus in vaccination does away with a number of dangerous possibilities, and for this reason it is constantly growing in popularity.

[The incubation stage of vaccinia being shorter than that of small-pox, the prompt vaccination of an unprotected individual who has been exposed to infection should always be practiced, if possible; oftentimes the severe disease may thus be prevented.]

2. The treatment of small-pox is purely symptomatic. When the disease has once begun it is too late for vaccination to have any influence upon its further course. During the initial period we may advantageously employ cool baths to diminish the fever and alleviate the constitutional symptoms. An ice-bag will relieve the headache. We must not let the lumbar pains lead us to any but a cautious use of local irritants, for the pocks come out in greater abundance upon such portions of the skin as have been in any way irritated. If the disease proves, during the stage of eruption, to be varioloid, there will be no further need of special treatment. Good nursing and proper food will suffice.

The true small pox, on the other hand, demands the interposition of the physician. He must strive to guard the regular course of the disease in the skin and in those portions of the mucous membrane which are accessible from being disturbed by secondary inflammations. For we have no doubt that the ruptured pustules furnish a most easy ingress to septic impurities from the surrounding atmosphere, so that later, when there is extensive suppuration of the skin, or analogous and severe disturbance in the mucous membrane, it is impossible to discriminate between the effects of the small-pox itself and those due to the secondary suppuration. If we were able to have the whole process go on "antiseptically" we should certainly have made an important advance in therapeutics. Indeed, the methods of treatment which have been up to this time recommended fulfill this

indication up to a certain point, e. g., painting the skin with tincture of iodine, or with a strong solution of nitrate of silver—methods formerly much in vogue. Schwimmer's suggestion seems still better. He recommends, from the beginning of the eruption, the use of a paste made as follows: Acid. carbol., parts 4 to 10; ol. olivæ, 40; cretæ preparat., 60. M. et ft. pasta mollis. This is spread on pieces of old linen and laid upon those parts where the eruption is apt to be worst—viz., the forearm, hand, and leg. The face is covered with a mask, having holes corresponding to the mouth, nose, and eyes. The applications are changed every twelve hours. Under this treatment the local distress is said to be diminished, suppuration slight, and healing comparatively rapid. The pain and sense of tension in the skin are often relieved by cold applications, or by simple ointment or oil. Under Hebra, in Vienna, continuous warm baths were employed in severe cases with great success.

The treatment of the affected mucous membrane in small-pox must also meet the indication above mentioned. The most thorough disinfection of the mouth and pharynx must be aimed at. The means to be used are careful washing and gargling with solutions of chlorate of potash (1 to 30), carbolic acid, borax, permanganate of potash, or liquor ferri chloridi. The eyes, if they need it, must also be appropriately treated. As to all other complications, cool baths are relatively the most useful remedy. They can be given without difficulty. The chief indications for them are severe pulmonary or nervous symptoms, or continuous high fever. Internal antipyretics, such as quinine or antipyrine, are also employed. Violent nervous disturbances, such as delirium, sometimes require the cautious use of narcotics. There is nothing to add as to the treatment of malignant hæmorrhagic small-pox, for, as we have said, such cases are unfortunately almost hopeless.

## CHAPTER VIII.

### VARICELLA.

(*Chicken-pox.*)

VARICELLA is truly one of the children's diseases. Adults very rarely have it. It is contagious, and often comes in epidemics.

The stage of incubation does not last over thirteen to seventeen days. The disease begins with the appearance of vesicles, the size of a pea or a little larger, usually having a small red areola, and varying in number from ten to one hundred or more. The trunk usually bears the greater part of the vesicles, while the extremities have few. The face is frequently the seat of a considerable number, and sometimes there are a few upon the hairy scalp. There may be a vesicle here and there upon the mucous membrane of the mouth or palate. There are seldom any prodromata. Slight symptoms of fever may attend the eruption itself. The eruption is usually over in a few days, although there may be repeated crops, so that we often see fresh vesicles by the side of others which are drying up. Each separate vesicle heals quickly, and the pustulation seen in small-pox is here exceptional. The course of the disease is completed in a week or ten days. Most children feel perfectly well the whole time, although there may be in rare cases pain in the limbs, anorexia, and a slight coryza. A severe complication is hardly ever seen. An unusual event is a mild nephritis.

Exceptionally, the disease may be rudimentary, with a varicelloid roseola and no formation of vesicles. On the other hand, some cases present quite severe constitutional symptoms and a high fever, even reaching 105° (41° C.) temporarily.

In most cases, however, as we have said, the child is so slightly disturbed that a physician is hardly thought necessary.

The **diagnosis** is almost always easy. Formerly varicella was often confounded with small-pox, and to this day the followers of Hebra, in Vienna, for some inconceivable reason, maintain the identity of the two. That they are essentially distinct is shown (1) by the epidemics of the two appearing entirely separate from each other, (2) by the fact that having one does not give immunity from the other, and (3) by the uniform failure of attempts to produce variola by inoculating varicella, or *vice versa*. Still, we must bear in mind, in order to avoid mistakes, that many dermatologists class the mildest cases of small-pox as varicella. Those who devote themselves to general diseases are probably all now convinced that varicella is a separate disease.

The **prognosis** is perfectly good. There is usually no special treatment necessary, but young children should be kept in bed till the eruption has dried up.

## CHAPTER IX.

### ERYSIPELAS.

(*St. Anthony's Fire.*)

**Ætiology.**—Erysipelas is an inflammation of the skin, excited by the presence of a specific, pathogenic micrococcus (*vide infra*), and recognized by redness, swelling, and pain. It has the peculiarity of spreading gradually, by direct extension, from its point of origin over a larger or smaller portion of the skin. There are two varieties commonly recognized—an idiopathic, or exanthematic, and a traumatic. The latter may follow any cutaneous wound if it be infected with the specific virus of erysipelas. Traumatic erysipelas is therefore a surgical disease, and will not be further considered here; nor shall we treat of puerperal erysipelas, a possible sequence to injuries inflicted upon the female genital organs during parturition; nor of the erysipelas of the new-born, which usually has its origin in the navel or in small fissures of the anus.

The so-called idiopathic erysipelas appears almost exclusively in the face, or at least it starts there. As it goes on it very frequently spreads to the hairy scalp, and not infrequently it also extends down upon the trunk. The clinical manifestations are perfectly characteristic. It is, however, a question whether idiopathic erysipelas is essentially different from the traumatic variety. There is good reason to suppose that facial erysipelas is really traumatic in every case, having its origin in injuries of the skin or mucous membrane, which are so small as to be overlooked. This view not only seems *a priori* very probable, but is supported by numerous cases. We see, for example, erysipelas taking its origin in excoriations of the nose or the borders of the nostrils, or in excoriations or fissures of the lobe of the ear. Quite often coryza precedes the erysipelas, and, in that case, the first inflammatory swelling of the skin is at the nose. The probable explanation of this fact is that the nasal catarrh is apt to cause slight erosions of the mucous membrane, and that these furnish an opportunity for infection with erysipelas. On the other hand, it can not be denied that there are cases of facial erysipelas where it is absolutely impossible to make out any cutaneous excoriation, and where there is an initial stage with feverish symptoms preceding the localized trouble in the skin (*vide infra*). Such cases suggest the thought that erysipelas is like the acute eruptive diseases, and that it is at least possible that infection may take place in some other way than the one mentioned.

The specific virus of erysipelas has been brought to our knowledge chiefly through the researches of Fehleisen. He has demonstrated a characteristic "chain-forming micrococcus" (*streptococcus erysipelatos*, *vide* Fig. 8) in the lymphatic vessels and serous canaliculi of the diseased skin. This micrococcus is distinguished by its peculiar behavior in pure gelatine cultures, and invariably causes erysipelas in the rabbits and the human beings that are inoculated with it.

FIG. 8.—The cocci of erysipelas.  $\times 700$ .  
Section through a lymph-vessel in the skin.

Facial erysipelas is most apt to attack the young, and seems to be somewhat more frequent in women than in men. The laity erroneously regard catching cold and getting frightened as frequent causes of the disease. If we except the predisposing causes above mentioned—viz., coryza, slight scratches, cuts, etc.—we usually find no cause of which we can feel certain. Often endemic influences are important. It has been long known that traumatic erysipelas can get so secure a footing in particular hospitals or wards that every wounded person treated in them is in danger of this disease.

But the apparently idiopathic variety is sometimes remarkably frequent in particular places. Likewise several members of one family may have facial erysipelas simultaneously. In nearly all such cases the sufferers are infected from some common source, for direct contagion is certainly exceptional. Direct inoculation can, however, as has been proved, convey the disease from a patient to other persons or to animals.

In contrast with the behavior of the acute eruptive diseases, erysipelas is peculiarly apt to attack the same individual over and over again. There are persons who have facial erysipelas about every one or two years. Often the explanation of this apparently lies in some chronic disease—e. g., chronic ozæna—which makes infection easy, but in other cases no cause can be discovered. Marasmus seems to predispose to erysipelas. At least we have observed that erysipelas occurred with relative frequency, in the Leipzig hospital, in patients suffering from the last stages of phthisis or cancer, or similar diseases.

**Clinical History.**—In many cases the first subjective symptoms are simultaneous with the cutaneous swelling, and these are chiefly local. There is pain and a sense of tension in the skin. Soon subjective symptoms of fever also appear, such as general malaise, anorexia, and headache. In other cases the disease starts with more violent constitutional symptoms: there is an initial rigor, with violent headache and great languor. Almost at the same time, or sometimes two or three days later, the patient notices that the face is swollen. In rare instances the disease begins with sore throat. We saw three almost simultaneous cases of facial erysipelas in one family, where a severe sore throat lasted for four or five days preceding the appearance of the cutaneous disorder.

The erysipelatos process in the skin is almost always circumscribed at first. It usually starts on the nose, less often upon the cheek, the ears, or the hairy scalp. The skin becomes considerably swollen, grows red, smooth, and shiny, and feels hot. The redness and swelling keep spreading. There is usually a sharp, elevated ridge, perceptible to sight and touch, separating the diseased from the still healthy portion of the skin. As long as the erysipelas is spreading, we see stretching out from its border, or somewhat removed from it, small red streaks and spots which

gradually increase in area and intensity, and finally coalesce. Any decided fold in the skin may hinder for a time the extension of the disease. The naso-labial folds are particularly apt to limit it. The border of the hairy scalp frequently forms a terminal line; but the whole scalp may be attacked, the inflammation stopping only when it reaches the nape of the neck. It is only in a relatively small number of cases that it spreads farther yet, attacking the back, the arms, and the anterior surface of the trunk, or even extending to the feet. This is known as *erysipelas migrans*. The facial erysipelas may be healed long before the disease ceases to extend over the other parts of the body. When the spreading process is about to cease, the inflammation usually becomes decidedly milder, appears only in isolated spots, and finally stops completely. In most cases, only the face, the ears, and a part of the scalp are attacked.

It is not a rare thing for vesicles or bullæ to form in the portions of skin attacked. Such cases are called *erysipelas vesiculosum* or *erysipelas bullosum*. The serum may change to pus in these blisters, and then we have *erysipelas pustulosum*. Exceptionally the infiltration of the skin becomes so intense as to result in a localized necrosis or gangrene—*erysipelas gangrænosum*. The parts most apt to be attacked by this are the eyelids.

Microscopic examination of the skin shows a marked hyperæmia of all the blood-vessels and a very considerable infiltration of both the skin and the subcutaneous connective tissue with serum and cells. In those parts where vesicles are formed there are many dead and disintegrated epithelial cells in the rete Malpighii. The presence of great numbers of the specific chains of micrococci has been already mentioned.

The inflammation in any one spot usually ends four or five days after it has made its appearance there. There is usually much attendant desquamation. The face is often left with a finer complexion than it had before.

The other symptoms, of which the constitutional disturbance and the fever are chief, correspond pretty closely to the severity and extent of the cutaneous lesion. It is comparatively seldom that this correspondence does not exist.

The fever in facial erysipelas usually rises rapidly at first, and to a considerable height. We have seen but few cases where the high fever was delayed till a day or two after the skin was attacked. The temperatures observed in erysipelas are often extreme:  $106^{\circ}$  ( $41^{\circ}$  C.) is not at all rare. The highest we ever saw was  $107.2^{\circ}$  ( $41.8^{\circ}$  C.). While the erysipelas continues or is spreading, the fever is seldom continuous, nor are the remissions insignificant. Pronounced intermissions, even down to normal, are very frequent, but are followed again by a rapid and great rise of temperature. The fever may terminate with a genuine crisis. In intense cases of considerable extent, or in *erysipelas migrans*, the termination is more apt to be by a more or less gradual lysis. We have seen the cutaneous inflammation in *erysipelas migrans* still extend itself a little, in a rudimentary form, after the fever had completely ceased.

The headache is often intense, and seems to result not merely from the inflammation of the scalp, but from disturbances of the circulation in the underlying parts. Other severe cerebral symptoms are also relatively frequent. The patient may be very restless, excited, and wakeful. At night there may be mild or even violent delirium; or there may be decided stupor. All these symptoms are in chief part due to the constitutional infection, or, to speak more accurately, to the intoxication caused by the infection; but they also justify a surmise, as we have said, that there is a circulatory derangement in the meninges and the brain itself, resulting from the inflammation of the scalp. In drunkards, delirium tremens is not infrequent.

One of the most constant symptoms in facial erysipelas is gastric and intestinal

disturbance. There is usually complete anorexia. The tongue is thickly coated. Vomiting is frequent, not only at the beginning but during the course of the disease. There is constipation; or there may be quite severe diarrhoea. There is no pathological lesion known corresponding to these clinical symptoms.

The entire duration of the disease varies greatly in different cases. A very light case may get well in a few days. Most cases of average severity last a week or ten days. Erysipelas migrans may continue for many weeks. We have several times seen a relapse come on after a number of days of complete apyrexia. Either the face would be once more attacked, or some portion of the skin which had previously escaped.

Local **complications** are comparatively rare in erysipelas. The lymphatic glands of the throat and back of the neck are very frequently somewhat swollen, but seldom attain great size. Bronchitis and lobular pneumonia may develop in severe cases, but are not at all characteristic. Some observers call attention to the occurrence of pleurisy, endocarditis, and pericarditis; but these complications also are probably secondary. The spleen is usually slightly swollen. Sometimes there is an icteroid hue. The urine frequently contains a small amount of albumen, and in severe cases of erysipelas acute hæmorrhagic nephritis is not so very rare. Swelling of the joints has been repeatedly observed. It is more frequent in the severe surgical forms of erysipelas, which are combined with universal septic and pyæmic conditions of the system. Purulent meningitis may complicate an erysipelas located in the head, but it is very rare. We should be exceedingly cautious about asserting its existence even when the cerebral symptoms are very pronounced.

Cutaneous complications are relatively frequent. We have seen herpes labialis quite often, and a number of cases of urticaria. Of much greater importance are the cutaneous abscesses which occur in severe cases. These are due to a phlegmonous or even gangrenous inflammation of the connective tissue. Their most frequent seat in the face is the eyelids, as already stated; and in that case the eye may itself be endangered. At the close of severe cases of erysipelas migrans, numerous abscesses may develop in the skin of the trunk and extremities, delaying convalescence.

The **diagnosis** of erysipelas is almost always easy when once the cutaneous lesion has developed. Phlegmonous inflammation of the skin and lymphangitis are to be eliminated; but this is always possible, with proper care. After a single examination, we may confound it with acute facial eczema of great severity, or even with a marked urticaria. Chief attention should be paid to the characteristic border of erysipelas and to its manner of extension.

The **prognosis** of facial erysipelas, when it attacks a healthy person, is very favorable. In drunkards a severe case may be complicated by delirium tremens, and the issue be unfavorable. We saw one case end fatally because of gangrene in the eyelids, followed by purulent inflammation of the orbital connective tissue. Erysipelas migrans may so exhaust the powers of feeble patients as to become dangerous. The prognosis of surgical erysipelas is relatively more unfavorable, but can not be considered here.

**Treatment.**—In a case of not more than average severity no special treatment is needed. To lessen the local discomfort, we usually cover the skin with powdered starch, or anoint it with olive-oil, carbolized oil, or vaseline. An ice-bag on the head is agreeable to most patients. If we wish to prescribe something, we may choose an acid mixture, as follows: Acid. muriat. dil., parts 8; syrup, 15; aquæ, 120. M.

In severe cases, however, the high fever and the nervous symptoms may demand our interference. The remedy to be chiefly recommended is cold baths,

of which two or three may be given in a day, and which most patients bear very well. The exhibition of quinine, antipyrine, or antifebrin is seldom called for, as there is a tendency to great spontaneous intermissions in the fever. If the facial inflammation proves to be part of an erysipelas migrans, the chief indication for treatment would be to check the unceasing advance of the disease; but, unfortunately, the means recommended for this purpose too often fail. It used to be customary to cauterize the skin along the border of the erysipelas with nitrate of silver, but this has been almost entirely abandoned as useless. Hueter recommends the injection of a two-per-cent. solution of carbolic acid beneath the skin at a little distance from the border of the inflammation. Although this is certainly a rational method of treatment, we have seldom seen any brilliant results from it. Of more benefit seems to be the newly recommended scarification of the diseased surface, followed by the application of a solution of corrosive sublimate. For internal use we mention first Pirogoff's camphor treatment. The patient takes every hour or two three grains (0.15 grm.) of powdered camphor and drinks large quantities of hot tea, to promote perspiration. In severe cases this method deserves a trial. Numerous other internal remedies have been recommended; but we need not enumerate them. We have not seen any influence upon the extension of the disease exerted by large doses of salicylic acid or benzoate of soda. In England a prominent remedy is liquor ferri chloridi (in the form of tr. ferri chlorid.), given to the amount of drachms jss.-ijss. in the course of the day (6-10 grm.). In the severe cases the main point, after all, is to maintain the patient's strength by nursing and food. If cutaneous abscesses form, they should be opened promptly, when they usually soon heal.

## CHAPTER X.

### DIPHTHERIA.

(*Diphtheritis, Croup, Cynanche contagiosa.*)

**Ætiology and General Pathology.**—Clinically, "diphtheria" means a certain well-characterized, specific, acute, infectious disease, the chief visible lesion of which is a croupous-diphtheritic inflammation of the pharynx and upper air-passages. In a purely pathological sense, however, the terms "croupous" and "diphtheritic" have a broader meaning. They denote a certain form of inflammation which may occur in the mucous membrane of almost any part of the body. It is frequent in the intestine and bladder. There is great diversity in the causes which may produce it.

The pathological characteristic of croupous-diphtheritic inflammation consists in the formation of a fibrinous exudation. This may either be a croupous membrane, which is grayish white, rather firm, elastic, and can be lifted off with comparative ease from the mucous membrane upon which it rests, or it may be a diphtheritic infiltration with necrosis of the tissues. Here the exudation is more or less deeply imbedded within the proper structure of the mucous membrane itself. There is no essential difference between croup and diphtheria; diphtheritic inflammation is the severer form of the disease, croupous inflammation the milder. In diphtheria the fibrinous exudation is preceded by a necrosis of the epithelium and of the underlying tissues of the mucous membrane as well, while in the case of croupous exudation the necrosis is limited to the epithelium. The croupous membrane never rests upon an intact mucous surface, but replaces the epithelium, which has already been totally or in very large part destroyed. Flaky remnants

of the epithelium, no longer nucleated, are sometimes found in the meshes of the fibrin. The preceding destruction of the epithelium is essential to the occurrence of fibrinous, croupous inflammation. The fibrinous exudation can be formed in those places only where the cause which excites the inflammation kills the epithelium at the same time. Apparently the epithelial cells have little if any share in the formation of the exudation. It is more probable that the material for the fibrin comes from the fibrinogen of the inflammatory matter which transudes through the walls of the vessels, and also from the disintegrated migratory white blood-globules. These last are abundant throughout the deposit itself, and still more numerous in the entire tissue of the mucous membrane beneath the croupous or diphtheritic exudation. If recovery takes place in croup, all that is needed after the exudation has been cast off is the renewal of the epithelium, which can be accomplished through the exclusive agency of the remnants of epithelium left along the borders of the diseased spot. In diphtheria, however, the entire necrotic portion of mucous membrane must slough off, a line of demarkation being formed, and cicatricial tissue replaces the necrosed portion.

The above is a bare outline of the present views about croupous and diphtheritic inflammations. They have been reached gradually through the labors of E. Wagner, Weigert, and others. We have not yet touched upon the ætiological factors; but what precedes renders it evident how manifold they may be, for many causes which destroy the epithelial layer of the mucous membrane, and at the same time promote inflammation, may excite croup. We have mechanical causes, such as impacted feces, gall-stones, renal calculi; chemical irritants, caustics, like ammonia and the acids; and, finally, a number of specific, infectious, disease-producing poisons. Among these is the specific poison of diphtheria proper.

Beyond a doubt the diphtheritic poison is organized. To demonstrate this, however, has been thus far extremely difficult, for there are in the diseased spots a great number of diverse micro-organisms, originating in the mouth and throat, and really secondary to the diphtheritic process; but, although they of course are entirely different from the specific "diphtheritic bacteria," it is very hard to separate them. The latest systematic investigations of Löffler have made us acquainted with a bacillus which can be found in most cases of diphtheria, while at other times it is very rarely found in the mouth. Löffler's bacilli are little cylinders with a peculiar club-like swelling at their ends. In croupous membranes they are found in colonies. Inoculated upon animals, they have a decidedly pathogenic power, and produce a disease similar to diphtheria. That they constitute the long-sought diphtheritic poison is therefore probable, but it is by no means conclusively proved.

Diphtheria is chiefly a disease of childhood. It is much less frequent in those over ten years of age than in earlier life. In the larger towns sporadic cases are occurring all the time, but now and then the cases become so numerous as to be endemic or epidemic. As to the precise way in which a human being becomes infected the opinions of physicians differ. We think it most probable that the poison reaches the pharynx along with the inspired air or in some other way, and here penetrates into the mucous membrane. It is very rare for the larynx to be the point of entrance (*vide infra*). It first excites a local disturbance, to which the general infection of the system (*vide infra*) is only a sequel. At the same time secondary infection plays often an important part in diphtheria, just as in many other infectious diseases. The seat of the primary diphtheritic process promotes and perhaps gives the first opportunity for a colonization of other varieties of micro-organisms; and these change for the worse the original character of the disease. It is especially probable that many cases of so-called "septic diphtheria" (*vide infra*) are due to a complication of the primary simple diphtheria.

with a septic infection. A confirmatory and remarkable fact has been discovered by Löffler. He has found in the diseased tissues of the throat, and also in the internal viscera, in severe cases of diphtheria, the same "chain-building micrococcus" with which, as the cause of certain severe forms of scarlatinal angina (see p. 39), we have already become acquainted. According to A. Fränkel, this organism is identical with the streptococcus pyogenes.

The original source of the infectious material is probably always some other case of diphtheria. Sometimes a direct, immediate transmission of the poison (contagion) is extremely probable—e. g., due to coughing, or to sucking out bits of membrane after tracheotomy. The latter is a comparatively frequent cause of the disease in physicians and nurses. The infection is often spread by some person who may himself escape the disease, or by fomites, playthings and other objects, to which the poison is adherent. The potency of the infectious matter is not easily destroyed by such external influences as desiccation or changes of temperature. In other words, it possesses great "tenacity." As to what extent the diphtheritic poison may have a power of independent reproduction outside the body—e. g., in the ground, or in the floor of dwellings—we remain in complete ignorance. Finally, we should notice that of late attention has been called to the possibility of catching diphtheria from diseased animals. Poultry, doves, and calves have diseases that are at least similar to diphtheria.

[While it seems in the highest degree probable that the poison is usually purely local at the start, cases occur which suggest that constitutional infection through the pulmonary blood-vessels may precede the local manifestations. Infection through the alimentary canal is not probable, though its occurrence can not be positively denied.

There are still points in the aetiology and pathology of this affection which are involved in obscurity. Much has been said and written in this country and in England about the relations of filth and diphtheria. That filthy surroundings contribute a soil favorable to the development of the poison, and at the same time diminish the resisting power of the human organism, can not be doubted; but, as long as the parasitic theory of infectious diseases prevails, sewer-gas and the like must be classed among the predisposing or accessory causes.

Some of the frightfully virulent epidemics of diphtheria in sparsely settled country districts and on the Western plains are difficult to explain under the theory that each case is mediately or immediately the result of a previous case; these difficulties will, however, doubtless be cleared away in time.]

**Clinical History.**—The incubation is rather brief, seldom exceeding two to five days. The disease itself almost always begins with general malaise, headache, fever, and pain on swallowing. Little children, however, often do not complain of this last symptom, and in older children the sore throat may not be very troublesome at first. It is therefore a very important rule for the physician to examine the throat carefully in every child who presents ill-defined general symptoms. If diphtheria is beginning, we find redness of the soft palate, and more or less swelling of the tonsils. Upon the inner surface of the latter, and perhaps upon the arch of the palate and the uvula also, are spots covered with a grayish-white coating, which is quite firmly adherent to the mucous membrane. They are less frequent upon the posterior wall of the pharynx and the hard palate. Their extent varies greatly in different cases. In the mildest they are chiefly confined to the tonsils, attacking the soft palate or the tonsillar surface of the uvula, but little if at all. In severer attacks the spread of the false membrane during the first days of illness is rapid. Almost invariably there is a very early and considerable swelling of the lymph-glands at the angle of the jaw. The constitutional symptoms persist. The children are restless. There is complete anorexia, and

frequently vomiting. The temperature-curve is not typical. It is irregular, but is often rather elevated, reaching  $104^{\circ}$  ( $40^{\circ}$  C.) or more. On the other hand, fever may be slight or almost absent, even in the worst cases. The pulse is very rapid. The urine may have a trace of albumen.

In mild cases the local and constitutional symptoms remain moderate; and at the end of a week or ten days there is decided improvement, with rapid convalescence. In severe cases, however, dangerous symptoms appear, perhaps early; the croupous inflammation involves neighboring organs, or a severe constitutional infection is developed.

The diphtheria very frequently extends into the nose. This "diphtheritic coryza," though not in itself dangerous, is usually a sign that the case is a severe one. The inflammation of the nasal mucous membrane may be simply mucopurulent, but it may also be croupous. It is betrayed by the abundant purulent discharge. Excoriations and superficial ulcers are usually soon produced at the edge of the nostrils. There may be nose-bleed.

A much more dangerous complication is the extension of the process into the larynx. This creates a mechanical hindrance to respiration, which proves fatal in a great many cases, as the child's larynx is so small. Formerly "croup"—i. e., croupous inflammation of the larynx—was regarded as a different disease from diphtheria. Many specialists in children's diseases still maintain this view; but it is in direct opposition to the teachings of pathological anatomy as well as of the clinical symptoms. We grant that there are cases where the pharynx is slightly affected, while the croupous inflammation of the larynx is extreme; and once in a great while the diphtheritic infection results in croupous laryngitis and tracheitis alone, the pharynx escaping disease. Still the proposition that there are two distinct diseases, "croup" and "diphtheria," is absolutely untenable. In the overwhelming majority of cases the throat is first affected and then the larynx. We should also consider how easily slight lesions in the pharynx might be overlooked, especially if located upon the posterior surface of the soft palate or upon the epiglottis. Cases of what is called "ascending croup," in which the laryngeal affection precedes the appearance of the disease in the pharynx, are, to say the least, very exceptional.

Usually hoarseness is the first indication that the diphtheria has attacked the larynx. Then follows the peculiar, harsh, ringing, "croupy cough," so dreaded by the parents, and, finally, there are signs of beginning laryngeal stenosis. Respiration is not much accelerated, but is labored, and the accessory muscles of respiration are called more and more into action. The child becomes more restless and anxious. Its face grows pale and livid. The chief cause of the dyspnoea is undoubtedly the mechanical stenosis due to the croupous deposit. Paralysis of the laryngeal muscles may perhaps be a factor. If portions of the false membrane become partially detached, they may act like valves, being sucked in at each inspiration, and pushed aside by the current of expired air. If stenosis occurs, respiration becomes noisy, resembling snoring. Inspiration, particularly, is prolonged and "sawing," and is attended by marked depression of the larynx toward the sternum. An important diagnostic point is the drawing in during inspiration of the supra-sternal region, the epigastrium, and the lower part of the sides of the thorax. This is the direct result of the obstructed flow of air into the lungs. As the lungs do not expand enough to correspond to the inspiratory dilatation of the thorax, the parts mentioned are forced in by atmospheric pressure. The degree of dyspnoea may vary at different times. The false membrane may be loosened and coughed up, rendering respiration easier for a time, till fresh exudations or displacements of membrane cause renewed distress. Recovery is still possible. The membrane may be expectorated and no more be formed. Unfortunately, this

happy termination rarely occurs. In most cases the symptoms of suffocation increase more and more, respiration grows quicker and more superficial, and the child becomes more and more stupefied by the excess of carbonic dioxide in the blood. The pulse gets very small, rapid, and irregular. There are mild convulsions and then death.

The autopsy in these cases discloses usually that the croupous inflammation has extended into the larger bronchi or even into the smaller. The lumen of the bronchioles may be almost completely occluded by false membrane. There is also sometimes a genuine croupous inflammation of the pulmonary parenchyma. Lobular pneumonia in the lower lobes is much more frequent, however. It is probably secondary and to be regarded as a pneumonia from inhalation. During life the pulmonary complications may be suspected, but can hardly be diagnosed. If we hear abundant moist râles over the lower lobes we are usually justified in supposing that lobular infiltration exists, even if there be no dullness on percussion. The croupous bronchitis as such gives rise to no especial auscultatory signs. If it is very extensive and reaches into the smaller bronchi, it may prove fatal, even if there be no laryngeal stenosis. This is more apt to occur in adults.

Another danger from diphtheria is through the general infection of the system, which may cause a fatal result. Although diphtheria does seem to start as a local disease, yet infectious matter (or poisonous substances) are certainly absorbed from the primary lesion into the general system. These exert their deleterious influences mainly upon the nervous system. We have already pointed out (p. 66) that the exact interpretation of these phenomena is rendered difficult by our inability as yet to distinguish between the effects of the primary and of the secondary infection of the body. Of especial practical importance are those cases in which we see the child sink into somnolence, and finally into complete sopor; its pulse becomes weaker and weaker, and more and more rapid, reaching 200 or more, and at last there is "paralysis of the heart" and death. All this occurs without any great degree of laryngeal stenosis. Such cases of severe constitutional infection, or "septic diphtheria," are most frequent when the local disorder in the pharynx is of unusual intensity, and the croupous exudation is replaced by deeper-reaching, necrotic, or even gangrenous inflammation within the mucous membrane. This has been called "gangrenous diphtheria." In such cases, also, the cervical lymph-glands are usually intensely inflamed. It must be noted that, exceptionally, a comparatively mild local disorder may co-exist with the worst general symptoms. A question of great interest, but which can not yet be answered, here presents itself. It is whether the constitutional symptoms are in every case directly dependent upon the diphtheria, or whether the diphtheria is not re-enforced by a peculiar, secondary, septic infection, proceeding from the diphtheritic ulcerations. We regard the latter view as probable. In adults the constitutional infection is a prime factor of danger, for in them laryngeal stenosis is less apt to occur, as the parts are so much larger than in children.

As to the part which the other organs play in diphtheria, we should mention that the process may extend not only into the nose and larynx, but into the Eustachian tube and the middle ear. It may also attack the anterior portion of the mouth, the gums, and the lips, or it may travel through the nose and the nasal ducts to the conjunctivæ. Very exceptionally the croupous process extends into the œsophagus. The infectious matter may be transferred, by the finger or in some similar way, to excoriations or accidental lesions of the skin, and excite diphtheritic exudations upon them. The frequent cases of inflammation of the eyes probably originate in the same manner, and also the diphtheria of the external genitals seen in children. With regard to other organs, it should be mentioned that there is not infrequently a splenic tumor. Intestinal complications (diar-

rhœa) are generally rare; nor is swelling of the joints frequent. The heart and kidneys, however, always need watching. It has already been stated that in severe cases of diphtheria the pulse becomes remarkably small and rapid. It is also often irregular. Further, even in cases that otherwise seem mild, sudden cardiac failure may occur, ushered in by excessive rapidity of the pulse, and often proving quickly fatal. This misfortune often happens at a time when convalescence seems to be fully established. Small islets of myocarditis are frequently found in diphtheria, but it is probable that the collapse is not so much due to them as to derangement of the cardiac nerves, particularly the vagus (*vide infra*). Renal disturbance betrays itself through the greater or less degree of albuminuria existing in most of the severe cases. It usually appears when the disease is at its height, less often at a later period. We often find a few casts in the urine, but seldom much blood. Œdema is rare. At the autopsy there is generally little macroscopic alteration of the kidneys. The microscope reveals the ordinary degenerative changes of acute nephritis (*vide infra*).

**The Nervous Sequelæ of Diphtheria.**—The convalescent from diphtheria is liable to be attacked by certain nervous sequelæ. Of these, diphtheritic paralysis is the most important. It appears about one or two weeks after the throat trouble ceases, or perhaps earlier, and it is quite as likely to follow mild cases as severe ones. It attacks the soft palate by preference. The tone becomes nasal and deglutition difficult. The naso-pharynx is imperfectly cut off during the act of swallowing, and with each attempt liquid regurgitates through the nose. Usually the pharyngeal mucous membrane is anæsthetic at the same time, and deprived of its reflex excitability. There may also be paralysis of the vocal cords upon one or both sides, and this again is frequently combined with anæsthesia of the mucous membrane of the throat. There may be paralysis of the ocular muscles, of which those controlling accommodation are most apt to be affected, rendering the vision for near objects imperfect. Paralysis of the muscles of the trunk and extremities is least frequent, but it may be very extensive. Sometimes several of these parts are paralyzed simultaneously. Thus we see quite often paralysis of the soft palate and of the muscles of accommodation combined. In some cases there is well-marked ataxia of the lower limbs with or without paresis. This renders the gait very uncertain and tottering, the tendon reflex is almost always abolished, while sensation is affected slightly if at all. Very rarely diphtheria is followed by contracture of the hands or other parts, by difficulty in articulation and paresis of the bladder. A paralysis of the pharynx is sometimes left behind, so that the children have to be fed for weeks through an œsophageal tube. It is a remarkable fact that not only in almost every case of the nervous disorders which we have mentioned, but often also in individuals who have entirely escaped them, there is no patellar reflex after diphtheria for weeks or even months. With regard to the pathological state, it is probably a degenerative condition of the corresponding peripheral nerves, not only in the post-diphtheritic paralysis, but also in the cases of post-diphtheritic ataxia. This harmonizes with the usually favorable termination of the nervous sequelæ of diphtheria. But there is one paralysis which is highly dangerous—that of the heart, as already mentioned. It may occur suddenly during convalescence. Probably it is analogous to the other nervous derangements, and the result of degeneration in the fibers of the pneumogastric.

**Diagnosis.**—The physician will seldom mistake a case of actual diphtheria if he pays proper attention. The characteristic deposit and the severe general and local symptoms make the diagnosis certain. It is much more common to take other forms of sore throat, particularly in adults, for diphtheria. The most deceptive are follicular and necrotic tonsillitis (*vide infra*). We must not suppose that

every white spot upon the tonsils is diphtheritic. The above-mentioned forms of sore throat are, however, frequent during epidemics of diphtheria, and even, as we have often observed of late years, in families where there are simultaneously cases of genuine diphtheria; so that the thought is suggested that they may ætiologically have some relation to true diphtheria. It is at any rate advisable not to omit proper precautionary measures, especially if there are children about.

(When the membranes are confined to the nose, the diagnosis may be more or less difficult; but it is especially in cases in which the nasal mucous membrane is involved that we encounter great swelling of the glands at the angles of the jaw. There is also apt to be a thin, acrid, bloody, or sero-purulent discharge.

Jacobi states that while diffuse pharyngeal injection may or may not point to imminent diphtheria, marked local congestion is either traumatic or diphtheritic. An examination of the urine should never be neglected in doubtful cases: in diphtheria a trace of albumen is very common; in simple or follicular sore throat albumen is very rare, if indeed, it occurs at all.)

**Prognosis.**—The unfavorable prognosis of the disease is universally known, even by the laity. The very fact that the best developed and healthiest children so often fall victims to it associates the name diphtheria with the saddest memories. There are indeed many mild cases which recover in a week or two, and severer ones which end happily in three or four weeks; but in most cases, where the process extends into the larynx, or the symptoms of a severe constitutional infection occur, medical interference has, unfortunately, no power to control the unfavorable issue. What the dangers are, and how recognized, can be well enough inferred from the preceding description of the symptoms. We will only remind the reader how carefully the physician should watch the behavior of the heart, since danger is apt to arise from this source, even when the case seems otherwise to be taking a favorable course.

**Treatment.**—If we take the ground that diphtheria begins as a merely local process, then local treatment of it certainly seems rational, at least at first. Unfortunately, the practical result bears out the theory very imperfectly. An actual and complete destruction of the croupous exudation is but seldom possible; and the attempt to accomplish this in a struggling child is so difficult and disagreeable that to-day most physicians have entirely abandoned the application with a brush of caustics or other substances to the throat. If it does, nevertheless, seem desirable to try energetic local measures at the commencement of the disease, the best agents to choose are a concentrated solution of argentic nitrate (1-10), or a solution of corrosive sublimate (1-1,000), or a mixture containing equal parts of carbolic acid and alcohol. If the disease has already made some progress, we may well spare the patient needless torture and consider that, by destroying the mucous membrane and by wiping off the exudation, we are likely to contribute to a further extension of the diphtheritic process. The author has not used energetic local treatment for years, regarding it as a useless disturbance of the patient.

We do not, therefore, regard active local interference as justifiable except at the very beginning of the disease; but we do believe that both then and at a later period it is extremely desirable to disinfect the mouth and throat as thoroughly as possible. Although this has little effect upon the diphtheria itself, it is at least a factor in preventing secondary septic infection, and thus of great therapeutic importance. Adults and older children should rinse the mouth and gargle frequently, using disinfectant solutions, e. g., of potassic chlorate or carbolic acid. Often, however, gargling proves painful. Inhalations are very appropriate. They are usually well borne when either lime-water (diluted with equal parts of distilled water) or simple salt solution is used, while the stronger disinfectants, such as a one-per-cent. or two-per-cent. solution of carbolic acid, often cause a

burning sensation. Nevertheless, it is advisable to keep up a carbolic spray in the neighborhood of the patient. We may sometimes try rinsing out the mouth with a fountain syringe, using for the purpose a weak solution of salicylic acid or some similar antiseptic. The frequent introduction of a few teaspoonfuls of cold water into the nose has also been recommended as an appropriate treatment—"cold nasal bath."

We shall mention only a few of the numerous other remedies which have been recommended. There is another local remedy, papayotin, which is obtained from the milky juice of a certain plant, and has the property of digesting albumen. If a diphtheritic exudation be frequently touched with a five-per-cent. solution of this, it will sometimes disappear rapidly; but the drug can not be shown to have an active influence upon the disease itself. Of internal remedies, we should mention potassic chlorate, which has been much vaunted as a specific, when given internally in rather large doses. We recommend it, but it should be used as follows: a half-teaspoonful of a two- or three-per-cent. solution should be slowly swallowed about every half-hour. The aim is to obtain, not a constitutional, but a local antiseptic action. It should not be given in larger amounts than *drachm j-jss.* (grm. 5-6) in twenty-four hours, lest it cause hæmoglobinuria or other toxic symptoms. Several physicians have lately recommended spirits of turpentine very highly, one half to one teaspoonful being given several times a day. It has not become popular. The same may be said of the internal use of potassic iodide. Injections of pilocarpine have also been praised. They are said to promote the detachment of the false membrane; but their efficacy is doubtful.

[The tincture of the chloride of iron is much used in this country in the treatment of diphtheria, and appears to be of real service; but it must be given in large doses. The following prescription is recommended by Jacobi, whose experience has been very large, for a child of two years:

R Tinct. ferri chloridi.....	3 ij;
Potas. chlorat.....	gr. xx;
Glycerin. pur.....	3 j;
Aque.....	3 v.
M. S.: Teaspoonful every fifteen, twenty, or thirty minutes.	

Turpentine is better as an inhalation than by the stomach; a teaspoonful or two of the oil can be poured in water kept at the boiling point by an alcohol-lamp. The whole air of the room is thus charged with the remedy. No drug should be used which disorders the stomach. Tablet triturates containing one one thousandth of a grain of corrosive sublimate can be allowed to melt in the mouth with the greatest freedom, and seem sometimes to exert a distinctly beneficial local action. The dose is, however, too small to secure the systemic effects of the drug unless the case is a mild one and free from notable dysphagia.]

If the larynx is attacked, and the consequent laryngeal stenosis threatens to cause suffocation, tracheotomy is our only resort. It is never indicated by the disease itself nor by the severity of the case, but only by persistent obstruction of the larynx. It is therefore not invariably easy to decide whether tracheotomy is called for in any particular case. If the general condition be bad and respiration already impaired, it may be very difficult to determine whether laryngeal stenosis exists. Tracheotomy will be of no avail if the croup has already extended to the bronchi, or if the dangerous condition of the patient is due to the severity of the constitutional infection or to incipient paralysis of the heart. This explains why the results of tracheotomy are not remarkably brilliant. On an average, only

about one third or one fourth of the cases operated upon get well; but even this number is enough to make us prize the operation very highly. How it is performed, and in what the after-treatment consists, must be learned in the text-books on surgery.

The attempt to expel the false membrane from the larynx by inducing vomiting is still often made, but seldom succeeds, and tortures and exhausts the child. Warm baths with cold douches may prove very beneficial. They excite deep respiration and more vigorous coughing, and also tone up the whole nervous system. The wet pack is also often employed, and sometimes with great benefit. Outward applications upon the throat are of little use. In general, we prefer the cold, wet compress to the ice-bag and ice-poultice, which are likewise often employed.

[Dr. Geo. W. Gay says ("Phila. Med. Times," 1884): "Not a single case of pseudo-membranous laryngitis has ever recovered in the Boston City Hospital without operation." In twenty years tracheotomy has been done one hundred and eighteen times with thirty-nine recoveries.

Four, if not five, successful cases were practically moribund at the time of operation.

Lovett and Munro bring the Boston City Hospital statistics down to Jan. 1, 1887. Tracheotomy for croup was done three hundred and twenty-seven times, all the cases but thirty dating from 1880. There was recovery in ninety-five, or 29.05 per cent. "The following table shows the recovery rate in cases operated upon within one, two, three, and four days after the beginning of the obstructed respiration":

Day of operation.	Number of cases.	Recovery.	Per cent. of recovery.
1	123	40	32.5
2	86	24	28.0
3	33	8	25.3
4	7	1	14.0

"Since Dr. Gay's article was written there have been two recoveries from moderate dyspnoea without operation. . . . Of forty-two patients under two years of age only three recovered."

Intubation, as devised by Dr. O'Dwyer, is a procedure which makes a distinct advance in the treatment of laryngeal stenosis. In permitting the free access of air to the trachea, intubation may save life without resort to the serious operation of tracheotomy; or it may tide over a time until tracheotomy becomes absolutely necessary or until the consent of the parents can be obtained to the use of the knife. In hopeless cases it may promote euthanasia. Of eight hundred and six cases collected and analyzed by Dillon Brown two hundred and twenty-one recovered, 27.4 per cent.]

In most cases of septic diphtheria, treatment usually proves completely futile. We must seek to avert cardiac paralysis as well as we can by stimulants, such as wine, camphor, and strophanthus, and endeavor to improve respiration and the condition of the nervous system by lukewarm baths combined with douches. Finally, we repeat that the physician should never neglect to maintain the patient's strength, as far as possible, by proper nourishment.

The nervous sequelae of diphtheria are best treated with the constant current. As an internal remedy, iron is good, and also nux vomica or strychnine. The last may be given subcutaneously, if desired, in doses of gr.  $\frac{1}{8}$  -  $\frac{1}{4}$  (grm. 0.001-0.002).

[Diphtheria is a disease which involves commonly much exhaustion, and too much stress can hardly be laid on the importance of administering the maximum

amount of nourishment in the most assimilable and easily swallowed forms from the start.

It is also important to give stimulants early in most cases, not waiting for signs of exhaustion. Enormous quantities of brandy can often be given to small children without the slightest toxic effect. No general rule can be laid down; the requirements of each case must be studied and met.

When painful deglutition interferes with nutrition, peptonized milk, eggs, brandy, and the like, must be given by the rectum. Rectal alimentation and stimulation are also to be resorted to in cases of post-diphtheritic paralysis of the oesophagus.]

## CHAPTER XI.

### INFLUENZA.

(*La Grippe.*)

INFLUENZA is a specific, acute, infectious disease which is especially distinguished by the enormous extent of its epidemics. While often years and decades pass without any especial attention being called to the disease, suddenly cases of it will appear with such frequency that the largest part of the population are attacked, and the disease may better be described as pandemic than epidemic. Pandemics of influenza can be traced back with certainty into the sixteenth century. In the present century the influenza during the years 1830-'33 traversed almost all of Asia and of Europe, then later there appeared numerous smaller epidemics, but these aroused general attention so little that the disease, upon its last pandemic appearance in the winter of 1889-'90 was almost unknown.

**Ætiology.**—Although we have every reason to suppose that the true cause of influenza is the infection of the body with a specific, organized pathogenic germ, yet this latter has as yet evaded discovery. It is evident that we have to do with some micro-organism which at certain times appears over an immense territory, the spores of which are probably scattered by the wind over large areas and are inspired with the atmospheric air by human beings. Many observations upon the appearance of the disease in isolated institutions (convents and the like) render it quite probable that the poison may also be carried by a person suffering from the influenza to regions previously unaffected. Nevertheless, this contagious manner of spreading plays no great rôle in comparison with the direct infection from the outer world, this latter mode being everywhere possible during an epidemic of influenza.

There is scarcely any reason for speaking of especial predisposing causes of influenza, inasmuch as at the time of a well-marked epidemic the overwhelming majority of the population are attacked, both the healthy and the diseased, the vigorous and the feeble. Sex certainly makes no difference, and age only to this extent, that the disease is seen more rarely in little children under one year old than in older children and adults. That catching cold has no special ætiological significance is evident from the fact that influenza often appears in patients who are already sick in bed.

It should finally be mentioned that animals also, and in particular horses, may be attacked by the influenza; but, nevertheless, it is as yet a doubtful question whether all the diseases in animals which are described under this name are actually identical with genuine influenza.

**Symptoms and Clinical History.**—The best general idea of the extremely manifold symptoms of the disease is to be obtained if we bear in mind that the influ-

enza causes both a marked infectious (or toxic) general constitutional disturbance of the body, and also certain local lesions with local symptoms. The clinical picture therefore varies greatly according to the predominance of one or the other group of symptoms, and also according to the special form of the local disease.

The onset of influenza is generally rather sudden. As a rule the marked cases begin with rather high fever, ushered in with a chill, violent headache, marked constitutional depression, and usually considerable pain in the back and loins. The weakness of the patient may be so great that, even if a vigorous individual, he will at once take to his bed. Severe nervous symptoms, such as stupor and delirium, are exceptional. Sometimes, but not very often, there is initial vomiting. The pains in the back are often associated with pains in the muscles and joints. Oppressive pain in the eyes is quite characteristic also. This is particularly felt upon moving the eyeballs, and therefore is probably located in the external muscles. The spleen is sometimes somewhat swollen, but any great increase in its size is exceptional.

If the clinical symptoms as the case progresses are mainly limited to the above-named constitutional symptoms—fever, languor, headache, pain in the muscles, we may speak of a typhoid form of the disease. Usually, however, certain local symptoms put in an early appearance, and it is especially the respiratory apparatus which is attacked. The precise symptoms vary considerably in different cases. Sometimes the upper portion of the respiratory tract, the nose, larynx, and trachea are involved; sometimes, from the start, the smaller bronchi. In the first instance there is marked coryza or hoarseness, in the other case there is cough, due to a dry bronchitis, which can be easily detected upon auscultation, and which involves especially the lower portion of the lungs. If these local symptoms outweigh the constitutional, the case is described as belonging to the "catarrhal form of influenza."

Sometimes the influenza is localized in the digestive apparatus. This "gastro-intestinal form" is much rarer than the catarrhal. In this case, in addition to the more or less strongly characterized constitutional symptoms, there is marked disturbance of the stomach and intestines, as shown particularly by nausea with persistent vomiting, diarrhoea, abdominal pain, etc. In one case we observed jaundice. We may also mention in this connection the appearance of an initiatory pharyngitis.

The already mentioned pains in the back, loins, and extremities may persist with unusual violence, and this peculiar form of the disease is known as the "rheumatoid." Probably the muscles and the muscular attachments are the chief seat of these pains, which may be so violent that the patient does not know how to lie, and sometimes keeps up a continual moaning. The loins, in particular, may be the seat of most acute pain, also the upper arms, the knees, the thighs, and the eyes. Objective changes in the painful parts, such as swelling of the joints, are scarcely ever seen, nor are the nerve-trunks as a rule especially sensitive to pressure. The painful muscles are usually weaker than normal.

The grouping of the clinical varieties of influenza under the four forms already named renders it easier to obtain a general idea of the manifold symptoms of the disease, but this division into separate forms must not be carried out too strenuously, for in reality numerous cases of the disease occur which present transition forms and combinations of the various groups of symptoms. Moreover, in all the forms a distinction must be made between mild and severe attacks, for in influenza, just as in most other infectious diseases, there are numerous rudimentary and mild cases as well as the fully developed ones, and some could not be properly interpreted but for the presence of the epidemic.

The duration of the disease is best determined by the duration of the fever. In the very mildest cases there may be no fever whatever, or simply a slight evening rise of temperature. As a rule, there is a moderate fever, say between 101.5° and 103° F. (38.5° and 39.5° C.), although higher temperatures even to 104° F. (40° C.) and more are not infrequent. In the beginning of every severe attack the fever rises abruptly. After a duration of several days, say four to seven, it may fall again in a manner approaching a crisis. More frequently, especially when there exists diffuse, catarrhal trouble in the lungs, the fever ends by lysis. With comparative frequency there are found to be noticeable deviations in the temperature curve: thus, for example, the high fever of the onset sinks on the second or third day, to be followed by an almost afebrile period of one or two days, whereupon a marked rise of temperature ensues. With this change in the temperature there are usually also corresponding variations in other symptoms.

We see, then, that the duration of simple, uncomplicated influenza is in the mild cases about three or four days, in the severer cases about seven to ten days. To be sure, we should also consider in this connection that convalescence is often surprisingly slow, so that the after-pains (as it were) of the disease are felt for weeks. These consist, for instance, in a certain degree of debility, and in painfulness of the muscles. Sometimes also there are complete relapses, so that directly or a short time after the disease has ended the symptoms begin anew. The special form of the disease may change in this case, so that, for example, the relapse of an influenza with predominant constitutional symptoms assumes the pronounced catarrhal form. Again, during the same epidemic it is not very rare for a patient to suffer from two attacks of influenza separated by a considerable interval of time.

**Complications and Sequelæ.**—While all the symptoms of influenza which we have thus far described are the direct effects of the original pathogenic cause, the majority of the frequent complications are undoubtedly dependent upon the ingress of secondary infection. The system when attacked by influenza is greatly exposed to these secondary influences, and almost all the dangerous and tedious cases of influenza become such only because of a mixed infection of this sort. This is particularly true of the lungs, in which secondary disease occurs most frequently—sometimes even in the first days of illness, but also in other cases later. The conditions here are similar to those seen in measles and whooping-cough. The simple, mild catarrh belongs to the original disease; the severe pulmonary affections are, however, invariably secondary complications occasioned by new pathogenic influences. These influences are not always the same. According to the investigations of Ribbert, Finkler, and others it is chiefly the pneumonia diplococcus and the streptococcus which are the true excitants of the secondary pneumonia seen in influenza. These cases of pneumonia are either extensive catarrhal pneumonia especially affecting the lower lobes, or more rarely croupous pneumonia with its characteristic sputum. The whole picture is then overshadowed by the pulmonary affection. The patient is oppressed for breath, has a severe cough, looks pale and cyanotic, and suffers from high fever. These symptoms persist for two or three weeks, and then gradually abate. It is in this way that influenza becomes dangerous for elderly and feeble or sickly persons. With noticeable frequency, pleurisy with effusion is conjoined with the influenza pneumonia. The exudation is generally serous, but exceptionally it is purulent.

Complications in other organs are less frequent. We should mention chiefly purulent otitis media and keratitis and other severe diseases of the eye. We have several times observed cases of acute nephritis, but this has always pursued a mild course. Among cutaneous eruptions herpes labialis is a frequent phenomenon in all forms of influenza, even the milder. Other exanthems, such as urticaria and

roseola, are much less frequent. Many of the complications named may continue even after the fever and all other symptoms have ceased, so that they must be regarded as sequelæ. This is particularly true of the diseases of the ear and eye and of persistent bronchitis, but only rarely of a pneumonia assuming the chronic form. An important and for the patient a troublesome and painful sequel is furunculosis, especially if the separate boils are located in the axilla or near the anus. Very often neuralgic pains in the distribution of the trigeminus or in the course of the sciatic or other nerves will persist for a considerable time after the influenza has ceased. But these pains may sometimes be located in the muscles; thus, for example, the frequent, persistent, and troublesome pain in the eyes.

**Diagnosis.**—The diagnosis of influenza is in general not difficult if one has to deal with a well-marked case. The characteristic initial symptoms of fever, headache, and pain in the loins are to be considered first of all. Their onset is much more rapid than, for example, in typhoid fever. Later on the pain in the various muscles as well as the catarrhal symptoms are the most characteristic phenomena. The diagnosis is very uncertain in many mild rudimentary cases. Often it is merely the fact of the prevailing epidemic that justifies one in calling these influenza. Nevertheless, one should be very careful not to make a diagnosis too quickly, and it is indubitable that during the time of an epidemic many cases are wrongly called influenza.

**Prognosis.**—For an individual who is healthy and vigorous, influenza is not a dangerous disease, even in its severer forms; for elderly persons or invalids it may, however, be a serious affection. Patients with heart disease or pulmonary disease, or those suffering from chronic nervous troubles, sometimes succumb to it; so that the general mortality at the time of a great epidemic of influenza is always considerably increased. The above-enumerated pulmonary complications are by far the most dangerous; less often is a fatal termination caused by general or cardiac weakness.

**Treatment.**—No specific remedy for the disease is known. Many physicians maintain that the exhibition of calomel at the beginning of the attack decidedly shortens its course, but confirmatory experience is wanting. In general we must, therefore, pursue a purely symptomatic method of treatment. For the initiatory fever, the headache, and the pain in the loins, antipyrine is sometimes a good remedy, and the same may be said also of quinine, phenacetine, and antifebrin. These drugs are also prescribed for the persistent pains in the muscles which come on later. Soothing liniments and ointments may be employed, with friction, for the same purpose. The treatment of the pulmonary complications is according to the established methods. Morphine is mainly used for the troublesome cough. Apomorphine, senega, and other expectorants may be employed, and, if indicated, external remedies such as an ice-bag or dry cupping. If the patient becomes very feeble, stimulants such as champagne and strophanthus are demanded.

---

## CHAPTER XII.

### DYSENTERY.

**Ætiology.**—By “dysentery” is meant a disease of the colon, which appears sporadically, but more often in epidemics; it is excited by infection with an organized pathogenic poison, about which we have as yet no further knowledge; and the infection is probably at first a local one. The true home of dysentery is in warmer and tropical countries, where the disease is much more

violent and wide-spread than here. For example, the mortality among the soldiers of the Anglo-Indian army due to dysentery is said to be thirty per cent. of the entire number of deaths. In our climate most of the epidemics occur at the end of summer and in autumn. Endemic influences are certainly important. The condition of the soil in some places is evidently very favorable for the development and dissemination of dysenteric germs, and that of other places is equally unfavorable. There can be no other explanation of the immunity of some localities contrasting with the great prevalence of the disease in others. How infection occurs we do not yet know. Dysentery does not seem to be directly contagious; but that it can be spread through the medium of the faecal dejections of the sick—e. g., from privies, chamber-vessels, and bed-linen—is very probable. Many cases were formerly referred to catching cold or to some error in diet; but we must, of course, regard these merely as predisposing influences.

The objective **pathological lesion** of the colon, in all severe cases, consists in a pronounced croupous-diphtheritic inflammation. The remarks as to the general pathology of such inflammations made in the preceding chapter are equally applicable to the analogous dysenteric inflammation. In this case, too, there is first a destruction of the epithelium and then the formation of a fibrinous exudation occupying its place, and penetrating down into the tissue of the mucous membrane itself. At the same time there is an intense purulent infiltration of the mucous and submucous tissue, accompanied by extensive ecchymoses. In the most virulent cases the macroscopic appearances are marked thickening of the whole wall of the intestine, congestion of the serous layer, and the conversion of the inner surface into a mottled, dark-red, irregularly roughened area of ulceration. The disease may be confined to the rectum and the sigmoid flexure, but in severer cases it involves the entire colon as far as the ileo-caecal valve, or even extends to the lower portion of the ileum. Besides this severe form of diphtheritic or even gangrenous dysentery, there is a milder variety, termed catarrhal dysentery. In this the mucous membrane is found in a state of intense purulent inflammation, with ecchymoses. Even here little masses of croupous exudation, which can be torn off, have replaced the epithelium; but they never form continuous layers of great extent. There is no sharp boundary-line between the two forms, the milder catarrhal-croupous and the severer diphtheritic dysentery. Numerous transitional and combined varieties exist.

We must remark, in conclusion, that precisely the same anatomical changes as are presented in true dysentery may result from other causes. Important among these is persistent faecal impaction in the rectum, which, by a purely mechanical effect upon the epithelium, may excite a diphtheritic inflammation in the mucous membrane. And any severe constitutional disease whatsoever, such as typhoid fever, measles, small-pox, septicæmia, or phthisis, may be attended by a so-called "secondary dysentery." This is most frequent in hospitals. Whether it has the same ætiology as genuine dysentery is uncertain.

**Clinical History.**—Throughout the entire illness the most prominent symptoms are intestinal. There may be first of all some slight irregularity of the bowels for a few days, and then appears a moderate diarrhoea. The stools are at first feculent, although thin, and number two to six daily. After a few days the discharges increase in frequency, and become extremely characteristic.

The stools are very frequent, occurring ten to twenty, and even sixty or more, times, in twenty-four hours. In severe cases there may be a distressing and almost constant desire to evacuate the bowels. After every operation, and to some extent during it, there is tenesmus attended by intense burning pain in the anus. The stools soon lose their usual feculent character in great part if not entirely. They become scanty, so that not more than about half an ounce is evacuated each

time. For the most part they usually consist of a sero-mucous fluid, in which are suspended numerous shreds and particles of varying size. These are blood-stained bits of mucus, little coagula of blood, and necrosed pieces of mucous membrane. One or another of these constituent parts may predominate, so that there may be slimy, purulent, or bloody stools, or all sorts of combinations of these varieties. We often find, besides, a few small masses of faeces, usually covered with mucus. We sometimes see numerous clumps of mucus, resembling sago or frog's spawn; they are probably mucous casts of the follicles. Under the microscope the greater part of the dysenteric discharge is seen to consist of pus-corpuscles and blood. There are also cylinder epithelium and an enormous amount of detritus, and the bacteria of putrefaction. A purely dysenteric stool has no bad odor, except that in the worst cases of gangrenous dysentery the discharges become blackish and extremely offensive.

The rectal tenesmus may be accompanied by a cramp-like pain during micturition. There are often violent attacks of colic. The abdomen is usually rather tense, and tender on pressure along the line of the colon, but without tympanites. The anus may be red, inflamed, and excoriated. Gastric symptoms are on the whole infrequent, if we except the complete anorexia which exists in all severe cases. Sometimes there is repeated vomiting. Occasionally hiccoughs prove distressing. The tongue usually has a dry, greasy coating.

The symptoms just depicted last about a week or ten days. If the case is of much intensity, the general condition is also greatly affected. The patient seems much collapsed, and is very languid and feeble, with a small and rapid pulse. The skin becomes cool and rough, the voice weak and hoarse. There is pain in the muscles. The patient wastes away. The temperature has little that is characteristic or typical. In many cases there is no fever at all, and the temperature may even be subnormal. In most cases, however, there is an irregular fever, seldom exceeding  $104^{\circ}$  ( $40^{\circ}$  C.), and having remissions.

In the worst cases the general weakness may increase more and more, and death occur; but with us a favorable termination is much more frequent. The distress gradually diminishes, the stools assume more and more of a feculent character, the patient becomes stronger, and after one and a half to three weeks convalescence is established. It may be a long while, however, before a patient completely recovers from a severe attack. A third possibility is the transition of the acute into a chronic dysentery. In this the symptoms of a chronic colitis, usually attended with cachexia, may persist for months and years.

Mild, rudimentary forms of dysentery also occur, presenting less violent intestinal symptoms, and recovering at the end of a few days. In these cases, too, great sensitiveness of the intestine to disturbing influences frequently persists for quite a long time after the illness. There may be exacerbations of the disease, and relapses.

**Complications** of dysentery, localized in other organs, are rare, at least in epidemics here. Abscess of the liver is mentioned oftenest by physicians in warm climates, and probably is best explained as the result of metastasis by way of the portal system. Articular disturbances also occur, and inflammation in the serous membranes. A few cases of peritonitis due to perforation have been observed, and a combination of dysentery and a "general scorbutic diathesis" has been described.

The **diagnosis** is rarely very difficult. It is based exclusively upon the intestinal symptoms and the character of the stools. It is only the cases of secondary dysentery which occur in the course of other severe diseases that can easily escape observation.

The **prognosis** is mainly influenced by the character of the epidemic, which as

we have said, is in our climate usually benign. There may be danger, particularly to elderly people, from bodily weakness and collapse.

**Treatment.**—Prophylaxis demands that the isolation of the patient and the disinfection of the stools be as complete as possible. The healthy must be very careful during an epidemic not to catch cold, and to avoid errors in diet, for experience shows that an opposite course predisposes to the disease.

The patient must be kept warm, and must not leave his bed, even if the attack be mild. The diet must be rigorous. If the strength is fair, thin porridge, milk, and broths suffice for some days. To a feebler person we should give somewhat stronger nourishment from the start, e. g., eggs, peptonized meat, and wine. Most patients bear liquids that are lukewarm better than those which are cold.

As to drugs, the habit of almost all experienced physicians is to give at first a mild laxative. Although opium does not usually control the diarrhoea and tenesmus at all, it is the rule for decided improvement to follow the exhibition of the laxative. During the first days, or, if need be, later, we give two to four tablespoonfuls of castor-oil daily. If this medicine is very disagreeable to the patient, we can replace it by a strong infusion of rhubarb (10-100). In southern countries large doses of calomel (gr. x to xv, grm. 0.5-1) are customary, and are highly praised by the physicians there. Further on in the disease we may content ourselves with giving *mistura amygdalar*; or we may administer bismuth in the following mixture: *Bismuthi subnit.*, parts 5; *mucilaginis acaciæ*, *syrupi simpl.*,  $\text{ãã}$  15; *aquæ destil.*, 120—to be shaken before taking. But if the disease should get worse again, we should always try a laxative.

Emetics at the beginning of the disease are often employed in the tropics, but seldom with us. *Ipecacuanha* (*radix antidysenterica*), given in large doses of fifteen to thirty grains (1-2 grm.), is even regarded by many as a specific. Numerous attempts have been made at local treatment by enemata. Yet no brilliant results can be claimed for any of these methods or medicines. A decidedly palliative effect can be obtained from the injection of thin starch to which twenty or thirty drops of laudanum have been added. Suppositories of cocoa butter containing extract of opium often mitigate the tenesmus. Other injections are recommended, each to measure  $\frac{3}{4}$  ij to ijss. (grm. 60-100), and to contain either *argenti nitrat.*, gr. j to vj (grm. 0.05-0.30), or *plumbi acetat.*, gr. ij to viij (grm. 0.1-0.5), or *potassii chlorat.*, gr. xv to xx (grm. 1-1.5). Many other solutions are used. The success of this treatment is, however, dubious. In all cases the margins of the anus must be protected from inflammation by frequently washing and anointing the skin.

The treatment of weakness and collapse is by the usual stimulants—wine, ether, camphor, and the like. In chronic dysentery the main point is to persevere in a strict control of the diet. We may exhibit astringents, such as tannin and columbo. Subnitrate of bismuth is also given, and nitrate of silver and acetate of lead. And in these chronic cases a long-continued and thorough use of rectal irrigation with fluids containing some mild astringent or disinfectant may have a good effect.

[Sporadic dysentery is a self-limited disease, and, as has been shown by Flint, runs its course within ten days without medication. Treatment, however, adds to the comfort of the patient and shortens the course. It is not customary with us to use daily laxatives. If there is any doubt as to whether the intestines have been emptied, a saline should be given, the action of which should be followed by opium in sufficient doses to allay pain and tenesmus. Subsequent action of the bowels is best obtained by simple large enemata. In weak persons castor-oil is to be preferred to salines.]

In epidemic dysentery active treatment is much more important. Laxatives

are contra-indicated by sero-sanguinolent dejections or by asthenia, but enemata can be freely used. Stimulation is often required; nutrition must be carefully looked after, such articles being chosen as are digested and absorbed by the upper portions of the intestinal tract, leaving as little residue as possible to pass on to the inflamed colon. Opium is often demanded and tolerated in large doses, and astringents, such as the acetate of lead, gallic acid, and the pernitrate of iron, are of service.

In acute dysentery the patient should be instructed not to yield to the desire to go to stool if he can help it, and tenesmus can often be much diminished by simple irrigation of the lower bowel with water, which may be warm or cold, whichever the patient finds more agreeable.

Chronic dysentery is one of the most difficult maladies with which we have to deal. In its treatment a sea voyage, or removal for at least some months to a climate other than that in which the disease originated, is of far more value than drugs.

#### AMEBIC DYSENTERY.

The amœba coli, first found by Lösch in the stools of a dysenteric patient, has received very careful study at the Johns Hopkins Hospital, and forms the subject of a most exhaustive and valuable monograph by Councilman and Lafleur.

The living organism is readily seen, and recognized especially by its active amœboid movements on the warm stage of the microscope. If the feces contain small gelatinous masses, these will be found to provide the most fruitful field for search. The numbers of the organisms vary widely in different cases, and even in the same case, from day to day. They are said to be present in this form of dysentery alone, and have been found in secondary abscesses of the liver and the lung, alike after death and during life. They should be sought for in all obstinate cases with dysenteric symptoms.

The prognosis is uncertain, and the cases are apt to drag along with exacerbations and remissions of the symptoms. But recovery does take place. There is notable danger of the formation of secondary abscesses, in which event recovery is hardly to be hoped for. The only treatment which seems to have been of much service—beyond a general hygienic and supportive regimen—consists in the use of copious injections into the intestinal canal of solutions of quinine, in the strength of one, to one thousand or even five thousand. Lösch found that contact with a solution of the latter strength for one minute suffices to kill the amœbæ.]

### CHAPTER XIII.

#### CHOLERA.

(*Asiatic Cholera.*)

**Historical Remarks.**—The home of genuine Asiatic cholera is India. The first epidemic with which we are accurately acquainted, and which was very widespread, occurred in 1817. The disease was probably endemic there at an earlier period. In the next few years the cholera spread in all directions, and reached Astrakhan by way of Persia. Between 1830 and 1832 the disease made its first great epidemic progress over Europe. Invading all European Russia, it reached Germany in 1831, and France and England in 1832. Then came many smaller epidemics up to 1838, when there was a complete cessation till 1846, in which year the disease, again starting from Asia, overspread Europe. There have since then

been epidemics in many places, but we can not here enter into the particulars of them. The last time that cholera occurred to any extent in Germany was in 1866, during the German-Austrian war. No one has forgotten the somewhat violent epidemic which prevailed a few years ago (1883 and 1884) in France and Italy.

**Ætiology.**—Some time ago it had become evident that the real cause of cholera consists in the infection of the system by a specific micro-organism. Koch was, however, the first to succeed in the search for the poisonous agent. He was in charge of the scientific expedition sent out by the German Government in 1883 to Egypt and India for the purpose of investigating the disease. Koch found in the intestines of all the victims of cholera whose bodies he examined a certain kind of micro-organism which he named the comma bacillus. It is shorter than the bacillus of tuberculosis, but somewhat thicker, and it is usually bent in the shape of a comma, or even like a semicircle (see Fig. 9). In the culture-preparations, the special peculiarities of which we can not give in detail, the comma bacilli grow into long spiral threads, resembling the spirilli of recurrent fever. Examined in a liquid, the individual bacilli are seen to make vigorous movements. They flourish best at a temperature between 86° and 104° (30° and 40° C.). Below 61° (16° C.) they cease to grow, but they are not killed even by a greater degree of cold. The free access of oxygen is absolutely indispensable to their growth. They multiply very rapidly in liquids—e. g., broth or milk—and they may, under favorable circumstances, retain their vitality for many weeks, while they can be readily destroyed by desiccation. In this again they resemble the genuine spirilli, which can maintain their existence only in fluids. An endogenous formation of spores, as we shall see below to be the case with the anthrax bacilli, does not take place, but Hueppe has established by actual observation that frequently two small spherical bodies appear on some indeterminate spot of the above-mentioned spiral threads, by which the continuity of the thread is interrupted. This process goes on until finally the thread is replaced by a considerable number of very minute round cells, which are apparently united to one another by a kind of jelly (formation of zoöglæa). It is certain that the round cells do not subdivide. The way in which they are formed corresponds with quite similar processes in other spirochæte. They are called "arthrospores," and perhaps represent a permanent form of the comma bacilli; for they resist desiccation and other injurious influences much better than do the comma bacilli themselves. By a process of growth the spherical bodies may, under favorable circumstances, give rise in their turn to new comma bacilli.

These discoveries of Koch have since been confirmed by all competent investigators, while the various alleged refutations of Koch's results have proved erroneous. It has been shown that in every case of genuine Asiatic cholera the comma bacilli are present in the intestine, and that they are never found under any other circumstances. Even the last postulate which was needed to show their pathogenic significance has been fulfilled. Rietsch and Nicati, followed by Koch himself, have succeeded in producing cholera in a guinea-pig by introducing into its duodenum pure comma bacilli.

Investigation as to the origin of cholera must, therefore, now meet this culminating question: Under what circumstances and through what channel do the comma bacilli penetrate into the human system, and in what manner do they there excite the characteristic processes of the disease? There can be no doubt that among us Europeans, and probably everywhere except in India, the cholera is invariably imported. It is equally certain that the dejections of cholera patients, which are rich in comma bacilli, are the chief if not the only agent by which the disease is spread. The bacilli which escape into the outer world with the stools

find abundant means to prolong their existence. They continue their growth upon moistened bed-clothes, or in water which contains a sufficient amount of organic substances, or in food, such as fruit or milk, or in moist earth; and the ways by which they can in turn enter the system of a healthy human being are infinite in number. It is easy to understand why certain persons—e. g., laundresses and nurses—are more liable to infection than others; and it is equally intelligible that the spread of the disease should often bear a relation to certain outward circumstances. The fact has long been a familiar one, that the cholera almost always progresses along the world's most frequented highways, and that it never travels faster than the means of human intercommunication render possible. This is important, because it shows plainly that the germs of the disease are not disseminated by currents of air. It is easy to understand that the distribution of the disease should sometimes correspond with that of water destined for personal use. Apparently in every case the disease-producing poison enters the intestinal canal, for the comma bacilli are found exclusively in the intestine, never in the other internal viscera; and this is true not only in the early but also in the later stages of the disease. We must therefore suppose that the bacilli are swallowed, and, if not destroyed by the gastric juice, develop their pathogenic functions in the intestine. In apparent agreement with this is the frequently observed fact that gastric catarrh, however acquired, existing at the time of an epidemic, always predisposes to the disease.

The views thus far expressed are opposed by Pettenkofer. He ascribes to the condition of the soil, varying with time and place, the chief rôle in the spread of cholera. He doubts whether the poison as contained in the stools is as yet efficient. It must, he thinks, undergo further development in an appropriate soil before it can acquire fresh pathogenic potency. His main argument is drawn from the fact that certain places, particularly those on rocky soil, enjoy immunity; the rarity of attacks upon shipboard is analogous. He points out that in cholera as well as in typhoid (*q. v.*) there is an evident harmony between the frequency of the disease and the varying stand of the water which underlies the surface of the ground. Further investigations, which will now for the first time have a firm foundation, afforded by the discovery of the comma bacillus, must decide how much influence the condition of the soil does exert upon the dissemination of the pathogenic poison. As it is, we feel certain that to give exclusive prominence to the condition of the soil, and to deny the possibility of infection in any other way, is to put a violent interpretation upon the observed facts; while the correctness of the above-stated views of Koch is becoming more and more probable. With regard to the constant presence of other micro-organisms than the comma bacilli in the intestine and the internal viscera of the victims of cholera, as claimed by Emmerich and others, we must regard them as associated appearances which have nothing to do with the true choleraic process.

Most cholera epidemics happen in the months of summer. Liability to the disease is very wide-spread, although some remarkable exceptions are seen. Sex is unimportant. Age has more influence. The disease occurs in sucklings, but,

FIG. 9.—(From Koch.) Comma bacilli from a cholera defecation which had lain for two days on a wet cloth. The S-shaped bacilli are at *a*, 600 diameters.

as a rule, is more rare among children than among adults. Elderly people are very apt to take the disease, while of typhoid fever the opposite is true. Most authors lay great stress upon predisposing causes. Among these, taking cold is not so important as are errors in diet and mild attacks of gastro-intestinal catarrh, which are shown by numerous observations to predispose strongly to the disease (*vide supra*). The stage of incubation seldom lasts over one to three days.

**Clinical History.**—As is the case in most acute infectious diseases, the intensity of the illness varies between the extremes of mildness and severity, so that usually a correct interpretation of the mildest cases is rendered possible only by the fact that an epidemic exists. These insignificant cases are called simple choleraic diarrhœa. The symptoms are those of a violent acute intestinal catarrh; the dejections are watery, rather large, painless, and number about three to eight in twenty-four hours. There is considerable malaise, complete anorexia, and thirst, and there may already be indications of severer choleraic symptoms—vomiting, slight pains in the calves of the legs, and diminished secretion of urine. Many cases recover after a few days or a week, but in others the first mild diarrhœa is succeeded, at the end of about one to three days, or rarely later still, by a severe attack of cholera. In such cases we speak of a "premonitory diarrhœa of cholera."

The mild form is succeeded in a gradual transition by the cases designated as "cholérine." Cholérine exhibits the symptoms of a violent, rather sudden cholera morbus. It often begins at night. To the diarrhœa, which now and then displays even at this time the characteristics of pronounced cholera, vomiting is soon added. The accompanying constitutional symptoms are rather severe. There is great languor and depression. The voice grows weak, the extremities are cool, the pulse is small and accelerated, painful cramps occur in the calves of the legs, the urine grows scanty and perhaps albuminous. The whole attack lasts about a week or two, till recovery is complete. The course of the disease is not infrequently varied by repeated improvements and relapses.

From these cases of medium severity there is again a continuous line of transition to the pronounced severe form of cholera proper. Statistics as to the frequency of the separate forms can not be given, since many of the milder cases escape observation.

The true attack of cholera may begin suddenly with the severest symptoms. As a rule, however, it is preceded, as already stated, by a first stage of brief premonitory diarrhœa. This, after one to three days, is replaced with equal suddenness by the severe symptoms of the second or "algid stage," or "cholera asphyxia." Its first symptoms are the abrupt appearance of great bodily weakness, chilliness, and vertigo. The characteristic gastro-intestinal symptoms soon declare themselves.

The diarrhœa grows very violent. At short intervals there are copious painless dejections, which at first retain somewhat of a feculent character, but very soon present a characteristic resemblance to "rice-water" or "whey." A single stool will measure a little less than half a pint (gm. 200). The stools have no color and almost no odor. They are watery, and usually deposit a finely granular, grayish-white sediment upon standing. Their reaction is neutral or alkaline. Only one or two per cent. is solid matter, with a little albumen and a relatively large amount of sodic chloride. In many severe cases the dejections contain more or less blood. The microscope reveals epithelium, triple phosphate, and numerous micro-organisms. Of these last a part are the comma bacilli, and a part are bacteria of putrefaction, etc. If the comma bacilli be demonstrated, of course the diagnosis is absolute. To accomplish this we take a coagulum of mucus from the stool, and, spreading it

upon a cover-glass in as thin a layer as possible, carefully warm the glass by passing it repeatedly through a flame, in order to dry the mucus and fix it in its place. The preparation is then stained with an aqueous solution of methyl blue. If the bacilli be very abundant, the microscopic examination suffices for their demonstration, although complete certainty about their identity depends upon their behavior in pure culture-preparations. These must therefore be instituted in all doubtful cases; but it would lead us too far if we entered upon the particulars relating to such cultures.

These excessive evacuations are but very rarely absent or nearly absent. They are more apt to fail if death occurs at the end of a few hours—*cholera sicca*.

[In *cholera sicca* the intestines after death contain the characteristic rice-water material which, perhaps owing to paralysis of the muscular coat, was not expelled during life.]

The appearance of the diarrhoea is soon followed by frequent though rarely distressing vomiting. The vomitus consists in part of ingested liquids and in part of an actual transudation through the mucous membrane of the stomach and intestine. Hiccoughs may accompany and follow the emesis.

In addition to these prominent digestive symptoms of vomiting and profuse diarrhoea, there are complete anorexia and excessive thirst. The tongue has a thick, dry coat. The abdomen is usually flat and soft, or it may be concave and hard. Sometimes we may feel fluctuation in the intestines, due to their being filled with fluid. There is not much real abdominal pain; what there is, is described as a "feeling of heat and pressure" around the umbilicus.

At the same time very severe symptoms develop in other organs. The circulatory system is chiefly affected.

The action of the heart may be stimulated at the beginning of the attack. The patient complains of palpitation and great precordial anxiety. After a brief time, however, cardiac weakness appears, and continually increases. The action of the heart becomes very weak, and the heart-sounds feebler and feebler. The pulse at the wrist grows very small, and is usually somewhat accelerated. In a severe case the pulse vanishes completely after a few hours.

This collapse of circulation makes itself quickly evident in the appearance of the patient. The face and extremities grow cool, and then ice-cold; the complexion becomes partly livid and partly a bluish gray; the lips are almost black. The surface temperature may fall below 95° (35° C.), while in the rectum febrile temperatures may often be observed, reaching 102° (39° C.) and higher. The eye and cheek grow very hollow, the skin becomes wrinkled, and loses all its elasticity. The voice grows hoarse and feeble (voice of cholera). Respiration is laborious and superficial. The mind may remain unclouded to the end, but usually there is great apathy, and all acuteness of perception is impaired. But few patients are restless and excited. Reflex action is much impaired.

One characteristic symptom is the cramps in the muscles. These are usually very painful, and consist in tonic contractions of the muscles, particularly those of the calf of the leg, but also those of the toes, thighs, arms, and hands. The cramps occur spontaneously or upon the least provocation, last a few minutes, and recur at short intervals. The precise reason of their occurrence is not yet known. It may be the effect of poison (*vide infra*). They can be observed in other severe acute diseases, although most marked in cholera. They sometimes occur in *cholera morbus*.

In a well-developed attack of cholera there is almost invariably oliguria or anuria. The urine, if any be secreted, is concentrated, with abundant sediment, and very often contains albumen. In many cases not one drop of urine reaches the bladder for days, and this condition persists till death or recovery.

The symptoms thus far depicted, if taken as a whole, represent the *algid stage*, which seldom lasts more than one or two days. In many cases death occurs during this period. It is ushered in by the tokens of extreme general prostration, and may take place after a few hours, or more frequently in the second half of the first day. But in other cases the "*stage of reaction*" succeeds. This may be a true compensatory period, leading directly to convalescence. The evacuations become less frequent and more feculent, and the vomiting ceases. The pulse becomes stronger, the cyanosis and coolness of the extremities diminish, and an abundant perspiration is not infrequent. After a few days urine is again excreted, which is almost invariably quite albuminous, and usually contains casts and red blood-globules. If convalescence be uninterrupted, however, the urine very soon becomes perfectly normal, and after a week or two the patient is to be regarded as completely recovered.

Departures from this favorable course of the stage of reaction are frequent. Recovery may be interrupted by repeated relapses into the previous condition, and sometimes with a fatal result. Or, instead of convalescence, there is developed a severe third stage, usually with fever. This stage ordinarily bears the generic name of *cholera typhoid*, although it is subject to manifold variations in its clinical symptoms as well as its exciting causes.

*Cholera typhoid* may present an actually typhoidal general condition with severe fever. There is a considerable elevation of temperature, headache, and dullness. The pulse is full and rapid, the face flushed. The skin, particularly that of the extremities, sometimes presents the so-called *choleraic eruption*, in the form of an erythema, roseola, urticaria, or the like. This variety of *cholera typhoid* ends after a few days in recovery, or else passes into one of the following conditions.

A second form of *cholera typhoid* is distinguished by the development of the most diverse local inflammations. Thus, there may be a severe dysenteric or diphtheritic inflammation of the small and large intestine, attended by offensive purulent and bloody stools. Pneumonia is also possible, as well as purulent bronchitis, diphtheritic inflammation of the larynx, pharynx, bladder, and female genitals, parotitis, and sometimes erysipelas and pyemia. And when we consider that, besides all these conditions, the usual intestinal symptoms, or those of *choleraic nephritis*, may exist also, it is evident how varied the clinical picture may be. The development of these local affections frequently lays the foundation for numerous sequelæ.

*Choleraic nephritis* gives rise to the third or *uræmic* variety of *cholera typhoid*. The secretion of urine is almost suspended. The little that is still passed contains numerous casts, albumen, and frequently renal epithelium and white and red blood-globules. Somewhere toward the end of the first week, or possibly earlier, there are grave nervous symptoms, to be regarded as *uræmic*: first there is headache and vomiting, then sopor and coma, or delirium and convulsions. Most of these cases are fatal.

**Pathology.**—We are now acquainted with the manifold symptoms and varieties of the disease. If we seek for the pathological changes which control the process, and endeavor to find some correspondence between them and the symptoms, we shall be disappointed. At least, in its early stages, *cholera* is merely a severe local disease of the intestine. We find the serous layer of the coils of the small intestine rose-red from congestion. The mucous membrane is in a state of catarrhal inflammation: it is swollen, reddened, and at first covered with a layer of tough, transparent mucus; but very soon an abundant transudation flows into the canal, so that the intestinal coils are filled with a large amount of clear fluid, looking like "*rice-water*" or "*gruel*," and so devoid of bile as to indicate the suspension of

its secretion. The signs of inflammation of the mucous membrane now grow more pronounced. The solitary follicles and Peyer's patches become swollen, with edges of a vivid red, and frequently there are many small ecchymoses in the mucous membrane. The extensive desquamation of the epithelial lining of the intestine has also been regarded as important, because it was regarded as in part the cause of the copious transudation. Still it may be questioned whether the desquamation is not, at least to some extent, a post-mortem change. In yet later stages of the disease the intestinal trouble very frequently assumes a croupous-diphtheritic character. The surface is necrosed and ulcerated in many places, and the contents of the intestine are no longer colorless, but sanious and bloody, with a foul odor.

Otherwise most of the post-mortem lesions correspond to what was obvious at the bedside. The muscles exhibit an early and persistent rigor mortis, and frequently contract in such a way as to throw the corpse into some unusual posture. All the internal organs are remarkably dry, pale, and anæmic. The left ventricle is contracted. The blood lies mostly in the large veins, the right side of the heart, and the cerebral sinuses. It is thickened, is but little clotted, and is said to resemble the juice of bilberries or huckleberries. The spleen is not enlarged—an exception to the rule in infectious diseases. The kidneys present marked passive congestion, most pronounced in the cortex. The microscope reveals a greater or less degree of parenchymatous nephritis, with great destruction of the epithelium. If death takes place at a rather advanced stage of the disease, the tissues have lost their characteristic dryness, and the most diverse local lesions, including nephritis, may be found to have occasioned death.

If we search for the connection between the pathological changes just described and the cause of the disease, or again between these lesions and the clinical symptoms, the first point to guide us is that the comma bacilli are found only in the lumen of the intestine, and never in the blood or in other parts of the body. The intestinal symptoms are satisfactorily explained by this abnormal state of the intestine, but for all the other grave symptoms we have to seek some special cause. The desiccation which the body undergoes as a result of the excessive liquid dejections can not fail to affect the tissues, but can not fully explain the symptoms, for at least the circulatory disturbances and the cardiac failure may develop before large evacuations have occurred. It has also been settled beyond question by means of the newer investigations that precisely the worst symptoms of cholera, namely, the muscular cramps, the subnormal temperature, and the changes in the blood, are occasioned by the chemical results of tissue metamorphosis in the comma bacilli, that is, by the so-called toxins. Many of these have been already isolated chemically by Brieger. In this connection the fact discovered by Hueppe is of the greatest interest, that the lack of oxygen which the bacilli in the intestinal canal must experience favors the abundant production of toxins.

As to the complications which occur in the later stages of the disease and which are embraced under the generic name of cholera typhoid, we regard them as mainly secondary. The choleraic process itself does not cause them, but is merely the occasion for their appearance. The examination of the intestine in such cases shows that numerous other varieties of bacteria follow closely upon the comma bacillus, gaining entrance to the system by treading in its footsteps.

The **diagnosis** of a pronounced case of cholera has no difficulties at the time of an epidemic. We must always be somewhat cautious about sporadic cases, for violent intestinal disturbance, simulating perfectly the milder forms of cholera, may be excited by other causes. In this connection we should mention the *cholera morbus* common among us; and poisoning, particularly acute arsenical

poisoning, may give rise to symptoms wonderfully like cholera. But now that Koch's discovery has been made, the diagnosis of all such doubtful cases becomes perfectly certain if we can demonstrate the presence of comma bacilli in the stools (*vide supra*). We have no doubt that this demonstration will also lead us to a decisive conclusion as to the aetiological importance of mild choleraic attacks.

The **prognosis** should always be guarded at the beginning, even if the symptoms be mild, for, as already mentioned, a simple diarrhoea may prove to be "premonitory" of a severe attack of cholera. During the real attack the prognosis grows graver in proportion as the case presents the characteristics of asphyxia and cyanosis. The mortality in many epidemics is frightful. All the inhabitants of a house or street may in a brief period be swept away. Minute statistics are difficult to give. If we count the typical cases alone, the mortality is not infrequently fifty to seventy per cent. In about two thirds of the fatal cases death occurs during the first days of the stage of asphyxia, and in about one third during the second period, known as "cholera typhoid." The influence of the diet and the hygienic surroundings of the patient before his illness is important. A greater proportion of children and old people perish than of the middle-aged.

**Treatment.**—The measures to be taken to prevent the spread of the disease, when it has once started in a place, we can not here discuss. We can merely say that the greatest care should be taken to have the ingesta pure, particularly the milk and water, that the further extension of the disease may be hindered simply by isolating the localities attacked as completely as possible, or at least regulating intercourse with them very strictly. We must try to prevent the communication of the disease by isolating individuals attacked, and by disinfecting the dejections with five-per-cent. carbolic solution, and likewise disinfecting everything that may have been contaminated by the excreta, such as linen and bed-clothes, for which dry heat is the agent. We must content ourselves with a brief mention of these facts. It is very important to disinfect the stools as promptly as possible, since Wood has discovered the remarkable fact that the cholera bacilli in the intestine, because of the lack of oxygen there, become much more sensitive to external influences although they produce more toxine, as stated above. Individual prophylaxis is of the greatest importance. It has been proved again and again that a mild intestinal catarrh will predispose to cholera, and will aggravate the attack if cholera does occur; so that the slightest gastric or intestinal disturbance at the time of an epidemic of cholera demands the greatest attention both as to diet and medicine. We may well quote from the last proclamation of the Prussian Department of Public Improvement (Cultusministerium), that, "by exercising and promoting cleanliness and moderation, each person will not only best protect himself, but also most efficiently support the efforts of the authorities in behalf of the common weal."

[The vital importance of the serious treatment of a beginning diarrhoea during a cholera epidemic can not be too strongly insisted on. Rest, simple diet, and a little medication will, in the vast majority of instances, entirely prevent serious consequences. The apparently trifling character of the symptoms is apt to lead people into a false security. Those who can leave an infected district should do so without delay.

With reference to the prevention of an epidemic, a pure water supply and strict cleanliness in its broad sense possess far more virtue than cordons of troops or measures of quarantine. It is more practicable to destroy the soil than to keep out the seed in these days of constant and rapid international communication. The systematic disinfection of all cholera discharges or articles soiled by them should be a matter of course.]

The drug chiefly used at the beginning of cholera is opium, which forms the chief constituent of the various "cholera drops." The best form is the tincture, in doses of ten to twenty drops, or gr.  $\frac{1}{2}$  to j (0.03-0.05 grm.) of powdered opium, repeated every two or three hours. A more complicated formula is: Tr. opii, 1 grm.; vin. ipecac., 3; tr. valerian. æth. [P. G.: valer., part 1; sps. atheris, 5], 10; ol. menth. pip., gtt. v. M. S.: Twenty to thirty drops. Or we may give tinctura opii benzoica [an elixir of which two hundred parts contain one part of opium, four of benzoic acid, and two parts each of camphor and oil of anise].

The opium treatment approved itself in the last epidemic, although a few physicians regard it as irrational, and prefer to give at the beginning of the disease one or two good-sized doses of calomel (gr. v to viij, grm. 0.3 to 0.5). Cantani and other Italian physicians praise highly enemata of a solution of tannin (warm water, previously boiled, two quarts (2,000 grammes); tannin, gr. xlv-xc (3.0-6.0); acaciæ,  $\frac{3}{4}$  ij (50.0); tinct. opii, gtt. 30-50) or some disinfectant. Hueppe advises large doses of salol internally.

When the attack is fully developed we usually continue the use of opium. The patient is wrapped up in warm blankets and subjected to friction; or warm oil may be rubbed into the skin. Hot tea may be given, or strong coffee, or broth, or mulled wine. Hot baths, to which mustard may be added, have proved beneficial in repeated instances. Vomiting is to be controlled by morphine or ice. The painful cramps in the calf of the leg require subcutaneous injections of morphine. The feebler the action of the heart becomes, the more energetic must be the stimulants employed. We may give champagne, or inject camphor or ether. The attempt has been made again and again to make good the loss of fluid by injecting a solution of common salt beneath the skin or into the veins. Samuel recommends for this purpose a solution containing six parts of sodic chloride and one part of sodic carbonate in one thousand parts of water, at a temperature of about 100° (38° C.). Finally, injections have been made into the peritoneal cavity of a 0.5 per cent. solution of sodic chloride, or in other cases of a 0.3 per cent. solution of sodic carbonate, and, it is claimed, with benefit.

Great caution must be exercised about the diet, not merely during the attack itself, but for a considerable time afterward. At first we can allow only thin porridge, milk broths, and possibly a soda biscuit. It is advisable to administer dilute hydrochloric acid with the food.

The treatment of cholera typhoid varies greatly, of course, according to the kind of attack. The separate affections should receive their customary treatment.

[In the first stage, absolute rest, opium, and lumps of ice by the mouth *ad libitum* are the chief measures on which reliance is to be placed. It should be remembered that the entire function of the intestinal tract is reversed; thus, instead of an absorbing, it has become an excreting surface.

In the stage of collapse the nervous system is more or less paralyzed, the blood is damaged by the loss of its watery constituents, and the circulation of that fluid is greatly impeded. The subcutaneous or gastric absorption of drugs is consequently delayed or suspended. The utility of any active internal treatment during this stage is very questionable. Certainly narcotism by opium is highly undesirable. Mild external stimulation and the tentative administration of ice and small quantities of champagne or food are, at all events, not likely to do harm. Nature sometimes reasserts herself when the conditions are seemingly desperate, and the third stage, or that of reaction, comes on. In this stage, careful nursing and a sensible symptomatic but in no way meddling treatment are most likely to be followed by good results.]

## CHAPTER XIV.

## MALARIAL DISEASES.

*(Intermittent Fever. Fever and Ague. Swamp Fever.)*

**Ætiology and Pathological Anatomy.**—Malarial poisoning is the best example of a purely "miasmatic" affection. The poison which produces the disease is without doubt localized in certain places, in which every human being is liable to become its victim. But if an infected person comes to a place free from malaria and not naturally favorable to its development, there is no danger that he will cause the disease in others. The disease is never caught through contact with the patient. It is not at all contagious; the malarial poison, after it has once penetrated into the body, has practically no opportunity to escape again in an efficient form from the diseased system into the outer world. But the blood of a patient injected into a healthy person may transfer the disease (Gerhardt and others).

If we except the polar zones, there are few regions where malaria is not endemic in certain parts, at least from time to time, if not constantly. There is, however, great variation in the virulence as well as in the number of cases. While the common forms of intermittent fever are very frequent in Germany, in numerous places, yet the grave forms of the disease are very rare. Other lands are notorious for the severe malarial diseases, e. g., Hungary, the lands lying on the lower Danube, the Roman Campagna, the Pontine marshes, Sicily, and numerous districts in other parts of the world, chiefly tropical. Numerous observations have only served to confirm the statement that the soil is the true home and cradle of the malarial poison, and that the virus, escaping thence into the lower strata of the atmosphere, may be taken into the system, probably during inspiration. Permanent dampness of the soil is essential to the development of the malarial poison. This explains why marshy districts are so often malarial. The ground must not be covered by a great amount of water, but must during the dry season lie exposed to the atmospheric air. The access of air to the moist soil seems to be a second essential condition for the development of the malarial germs. A third influential factor is the temperature of the air, as proven by the great prevalence of the disease in southern countries and in the summer season.

With regard to the nature of the malarial poison, the work of late, and in especial of Italian, investigators (Marchiafava and Celli, Golgi, and others), has led to interesting conclusions. According to these authorities, the generators of malarial disease, the malarial "plasmodia," belong to the lowest class of animal life, the protozoa, and to that subdivision known as sporozoa. The plasmodium enters the blood and penetrates the red blood-corpuscles, where it has a lively amœboid motion. It evidently lives upon the tissue of the red corpuscles. The hæmoglobin of the latter is thus changed into melanin, a substance which apparently contains no iron, and the black granules of which are usually seen in the body of the plasmodium. After the red globule occupied by the plasmodium is completely destroyed, the micro-organism becomes free in the blood-current. Particles of pigment collect in its center, while on its periphery new generations are formed by splitting and subdivision. These new bodies appear to be mainly present in the spleen, liver, and marrow during the afebrile interval; while at the time of the paroxysms of fever they enter the blood once more and penetrate into the red globules. It is a very interesting fact that the different forms of intermittent fever, and in especial the tertian and quartan varieties, probably owe their development to different kinds of plasmodia, in which the developmental phases occupy different lengths of time. We can therefore by means of inoculation transfer from one human being to another only that variety of intermittent

which the first patient exhibits, whether tertian or quartan. The quotidian type is probably due to the development of two cases of tertian fever in the same individual, side by side; whereby each separate tertian owes its development to a special generation of the plasmodium. It is Golgi's view that the severe tertian forms of malaria are caused by a special variety of plasmodium, which is distinguished by the appearance of crescentic forms of development.

Although no one has yet been successful in establishing this view of the plasmodia by means of pure cultures and inoculation of the same, yet the relation of the plasmodium to malaria seems evident from the fact that in every patient with malaria the plasmodia can be easily demonstrated in the blood (even without any staining), while these same forms are never detected in the blood except in malaria. The way in which the plasmodia enter the human body is not yet known. It may be by inhalation or by the stings of insects.

The investigations with regard to the plasmodium of malaria have also explained the long-recognized fact that in chronic malaria large amounts of pigment collect in the internal viscera. These deposits are most abundant in the spleen, which in the chronic varieties of the disease develops into a firm, hard tumor; but they are also found in the bone-marrow, liver, brain, and kidneys, leading finally in the liver and the kidneys, in frequent instances, to processes of chronic degeneration and inflammation. It is especially noteworthy that in those patients who present the most marked cerebral disturbances (pernicious comatose fever, *vide infra*), the cerebral capillaries are found to be completely occluded with pigmented plasmodia.

[Periodical fever is very widely distributed in the United States, and in the southern portions occurs in severe though not in the severest forms. Some regions which were formerly free from it are no longer so, and, *vice versa*, some regions which were greatly subject to it are now exempt; these changes are closely connected with the clearing and upturning of virgin soil largely impregnated with decaying vegetable matter, and with the subsequent cultivation of the same for considerable periods of time. The poison does not extend far above the surface of the ground, as is shown by the relative safety of sleeping in the upper as compared with the lower story of a house; during the night the poison seems to exist in greater intensity than during the day. Attacks are more liable to occur during the spring and autumn than at other seasons.

The hopes which have been entertained in some quarters that malarial regions might be rendered healthy by large plantations of the Australian eucalyptus globulus, a rapidly growing tree which absorbs immense quantities of water, do not seem likely to be realized in the light of French experience in Africa, and in that of the Trappist monks in Italy.]

Klebs and Tommasi-Crudeli have made extensive investigations as to the nature of the malarial poison. We must regard it as organic. The authorities just named state that the true cause of malaria is a specific variety of bacillus. They found peculiar bacilli and their spores both in the earth of malarial regions and in the adjacent strata of the atmosphere; and, by infecting rabbits with these, they were able to induce attacks of fever, swelling of the spleen, and the characteristic formation of pigment matter (*vide infra*). Before this, bacilli and spores had been found in the blood and spleen of patients suffering from malaria. It can not yet be said just how much significance these discoveries have.

[To Laveran really belongs the credit for the discovery and accurate description of the plasmodium. His work in Algiers has been substantiated by observers in widely separated malarial regions, and, at the same time, no very important additions have been made to it.

It is difficult to overrate the diagnostic and therapeutic importance of this dis-

covery. The ordinary intermittents are usually easy of diagnosis, but the remittent forms often simulate typhoid fever, while the pernicious form may resemble uræmia or intracranial disease. Especially in pernicious cases life may be saved by prompt and appropriate treatment, which must be based, of course, on accurate diagnosis. The following details may be of use to those who are not familiar with the method of blood examination. The finger tips should first be scrubbed with a nail-brush, and soap and water, and then washed in alcohol or ether, to obviate the danger of mistaking minute particles of dirt for the pigment-granules derived from the destruction of red blood-corpuscles. A portion of a drop of blood is then to be received on a scrupulously clean object- or cover-glass, and squeezed out between the two, so that a thin layer of blood with separation of the individual corpuscles is secured. The amœboid forms of the plasmodium retain their movements for a number of minutes in a warm room, much longer, of course, with a warm stage. The presence of pigment granules in the red corpuscles may be the readiest indication of the presence of the organism. The crescentic forms are found more especially in chronic cases which have been under treatment by quinine, as is stated by Osler. Many of the other forms can be found in the blood only during a paroxysm. The editor has seen them in abundance in a cachectic malarial patient from Panama, and failed to find them again after a single large dose of quinine, which terminated the chills.

In dried and stained specimens it is easier to detect the organisms, but amœboid movement is, of course, lost.]

Liability to the disease is very wide-spread. No race, no age, no sex, enjoys immunity. It is a noticeable fact that those who have had the disease once are all the more apt to have it again. Former patients, although they feel perfectly well in a non-malarious region, are very liable to fresh attacks, or at least much discomfort, as soon as they re-enter an infected district. The time of incubation does not seem to be constant. It is put at from six to twenty days, but may be shorter. We shall consider below chiefly the common forms of intermittent, such as appear among us in Germany, contenting ourselves with a very brief description of the severer forms.

#### VARIETIES OF MALARIAL DISEASE.

1. **Intermittent Fever.**—This is the simplest form, and has for its especial characteristic the relative brevity of the febrile attacks, which almost always exhibit a remarkably uniform type. A febrile attack of this kind is frequently the very first symptom of the disease. In other cases the paroxysm of fever is preceded by a prodromal stage lasting several days, during which the patient feels languid, has no real appetite, complains of headache and pain in the back of the neck and in the limbs, and often even thus early presents a slightly yellowish complexion and an enlarged spleen.

In the typical attack of intermittent fever there are three stages. The attack begins with a chill. There is pronounced malaise, attended by intense chilliness and more or less shivering. The skin is cool and pale, the face may be somewhat livid. The temperature of the interior of the body is elevated, and rapidly rises higher. In by far the greater number of cases the attack occurs in the morning, or at least before noon, and but seldom later in the day. This cold stage varies greatly in length, usually lasting an hour or two.

The chilliness is followed by the hot stage. The skin grows burning hot, the face flushes, the pulse, which was before small, becomes full, and the action of the heart is excited. At first the temperature continues to increase, and reaches in this stage its maximum for the attack. It is exceptional for it to remain under 104° (40° C.),

and by no means rare for it to touch  $106^{\circ}$ , or even  $107^{\circ}$  ( $41^{\circ}$ – $41.5^{\circ}$  C.). This stage almost always lasts longer than the preceding, generally about three to five hours. The temperature may begin to fall as early as the latter part of the hot stage, but may persist till the beginning of the third stage.

In this, sweating, stage the skin grows moist, and there is soon a profuse general perspiration. The patient begins to feel much better. In a few hours the temperature usually becomes normal, and, after lasting in all about eight to twelve hours, the attack is over. It may be shorter or rarely longer. Usually, however, the temperature keeps on sinking slowly, so as to be still subnormal even on the next morning, perhaps not above  $97^{\circ}$  ( $36^{\circ}$  C.).

There are certain peculiarities in the temperature-curve which we have ourselves observed. The elevation of temperature is almost invariably more rapid than its decline. The rise is most rapid during the first hours of the cold stage, and slower during the first portion of the hot stage. The ascent is but very seldom interrupted. During the hot stage, when the fever is highest, in the neighborhood of  $106^{\circ}$  F, ( $41^{\circ}$  C.), there are not infrequently two little summits to the fever-curve, if the temperature be taken at short intervals. But the temperature may for hours remain the same. The temperature generally begins to fall some little time before the perspiration is evident. The decline is slow. It may be perfectly continuous, or it may be interrupted by fresh elevations, which are sometimes slight and sometimes considerable. In many cases the descent is by steps, the temperature remaining the same for half an hour or an hour, and then abruptly falling a couple of degrees and remaining for a time at this new level.

The chief characteristic is not, however, the nature of the single attacks, but the peculiar manner of their repetition. If the case is not under treatment, the single attacks keep recurring for a time, either daily, as in the quotidian variety, or every second day. This latter type of tertian intermittent fever (cf. Figs. 10 and 11) is probably the most frequent. There may exceptionally be still longer

FIG. 10.—Quotidian intermittent fever.

FIG. 11.—Tertian intermittent fever.

[Chinin 2.0 = Quinine, 30 grains.]

afebrile intervals. Thus we have *quartans*, *quintans*, etc. If there are two attacks in one day, a rare event among us, we have a double quotidian. If there is a violent attack every second day, and on the intervening days there are milder

attacks, it is a case of double tertian. Very often the attacks do not recur at just the same time of day, but a few hours earlier each time. Less frequently they are later. This peculiarity is expressed by the term "anticipating" or "retarding," as the case may be—e. g., a retarding tertian ague. In cases of long standing, the paroxysms may finally lose all regularity, so that the fever is described as "erratic."

Next to the febrile attacks, the swelling of the spleen is the most constant and important symptom. It is usually considerable and capable of demonstration by percussion and palpation. At first the tumor increases with every fresh attack, and diminishes but little during the intervals. After the patient is freed from his attacks of fever the spleen may continue enlarged for some time. It is tender on pressure. The liver may likewise be swollen, but this is less constant and also less important.

Certain changes in the skin are very characteristic, chief among which is a peculiar yellowish-brown discoloration. This is due to an abnormal deposition of pigment in the skin. Herpes on the lips or nose is seen very frequently during the attacks. We have seen one case of herpes on the cornea. Mention has also been made of urticaria, purpura, and other eruptions.

Other internal organs than those already spoken of are rarely much disturbed. One symptom should be mentioned, which we have ourselves seen several times, viz., a quite marked acute dilatation of the heart during the attack. There were no bad results, and the normal condition was soon re-established. We may hear during the attack functional cardiac murmurs of a blowing character. Thoracic examination, particularly if made during the attack, may afford the signs of a dry bronchitis. Sometimes there is considerable diarrhoea, or other evidence of intestinal derangement. Catarrhal jaundice is confined to the severer cases. Sometimes the urine has a moderate amount of albumen. Genuine nephritis is met with only in the graver varieties of the disease. The increased excretion of urea on the days of the fever results, as in any fever, from the increased destruction of albumen. Severe pain in the cervical and upper dorsal vertebrae is regarded as characteristic of intermittent.

Besides the typical attacks, rudimentary and modified ones are not rare, in which the separate stages are ill defined, or in part wanting. We are most apt to see this in cases which have been already treated with quinine. Children do not have a true rigor. They merely become pale or livid. They may present marked nervous symptoms.

**2. Pernicious Intermittent Fever.**—This dangerous form occurs only in the true malarial districts, and is often preceded by a few attacks of a milder character. Then appear, in addition to the more or less perfectly marked stages of the febrile attack, other graver symptoms which not infrequently end in death. Severe nervous symptoms are most frequent. There may be unconsciousness, coma, delirium, or epileptiform or tetanic convulsions. None of these symptoms persist longer, as a rule, than does the common sort of an attack, and in a favorable case vanish completely when the sweating, which is usually profuse, begins. The great danger comes from the recurrence of the attacks. A second form of pernicious intermittent fever causes violent gastro-intestinal symptoms, which may almost exactly imitate the algid stage of cholera, with vomiting, diarrhoea, and collapse; or there may be severe cardialgia, dysentery, and the like. In the so-called pernicious intermittent with jaundice, intense jaundice appears during the attack, with vomiting and diarrhoea, and sometimes the gravest nervous symptoms. There are certain very peculiar forms, in which local diseases, such as pleurisy or pneumonia, can be demonstrated during every attack, but vanish wholly or in part when the temperature declines, only to appear again during the next attack.

[The pernicious form occurs in isolated cases wherever the ordinary variety of the disease prevails, but is much more common in the Southern and Western States, and there varies in frequency in different years. Periodicity in the attack is not always observed. The pernicious character is not always manifested in the first attack, one or more mild paroxysms being often precedent. In this country the algid form of pernicious periodic fever is often called "congestive chills," and this form is more common than the comatose or another form not mentioned by the author—the hæmorrhagic. In the latter the blood escapes from the kidneys, and less constantly from the mucous membrane. During the late civil war the mortality in the white soldiers of the United States army from pernicious malarial fever was 23·91 per cent.]

3. **Remittent and Continuous Forms of Malarial Fever.**—These are generally severe, and are seen, like the preceding, only in the worst haunts of malaria. The proof that they have the same ætiology as intermittent fever lies in the fact that they are sometimes developed out of the milder forms; but it is to be noticed that many types of disease which physicians in the tropics describe as malarial affections have not yet been proved to our satisfaction to have an actual identity of origin with the common intermittent fever. The symptoms of this variety are likewise those of a severe constitutional infection. Gastro-intestinal symptoms may predominate; or there may be such grave nervous symptoms as coma, delirium, and convulsions; or there may be jaundice, hæmaturia, and even a general hæmorrhagic diathesis; or various local disorders may exist, such as pneumonia, nephritis, and hepatic and splenic abscesses. The fever is high, but without any sort of regular intermissions, maintaining for one or two weeks a remittent or a tolerably continuous type. Milder forms may end in recovery after eight to fourteen days, but often death ensues at this time, or even earlier.

[The remittent form apparently shows a greater intensity of the poison or a greater susceptibility of the individual. In the United States army, from 1861 to 1866, its mortality was twelve times as great as that from the intermittent form.]

4. **Chronic Malarial Cachexia.**—This occurs in the true malarial regions, and affects not only people who have had frequent attacks of pronounced intermittent or remittent fever, but also those who have never had acute attacks. The condition is chronic. It may exhibit a genuine intermittent character. The patient usually has a decidedly yellowish, malarial complexion, and almost always the spleen is evidently enlarged. There are no regular febrile attacks, but merely symptoms of general debility, anorexia, tendency to diarrhoea, or, more rarely, constipation, vertigo, wakefulness, frequent perspiration, pains in the muscles and joints, dyspnoea, and palpitation. There may be such nervous symptoms as trembling, paralysis, and mental disturbance; or we may see intestinal symptoms and jaundice. Dropsy occurs; also epistaxis, cutaneous ecchymoses, and other signs of a scorbutic condition. The spleen and liver gradually become greatly hypertrophied and melanotic. At the same time there may be an irregular fever, approaching either an intermittent or a remittent in type. Finally, secondary diseases are possible—e. g., tuberculosis, amyloid, or dysentery—and these may prove the immediate cause of death. The milder forms may be cured, but seldom unless the patient abandons for ever the malarial district.

5. **Masked Intermittent.**—This is the designation of cases where, although there is no fever, certain other disturbances arise in regular intermittent attacks. Chief among these is neuralgia. Its favorite seat is the supra-orbital branch of the trigeminus. It may occur in the other branches of the same nerve, or in the sciatic, the anterior crural, the nerves of the brachial plexus, and elsewhere. Cardialgia and enteralgia may occur in the same way. These attacks last from thirty minutes to several hours, and are frequently associated with all sorts of constitu-

tional symptoms, but, as we have said, are afebrile. There may be a splenic tumor, which aids diagnosis; but this sign may be wanting.

Numerous other intermittent disorders besides neuralgia have been described as masked intermittent. The list includes anæsthesia, convulsions, and paralysis; also intermittent hæmorrhage, œdema, cutaneous affections, and intestinal symptoms. We must add, however, that those who have described diseases of this sort, some of which seem strange enough, have not always been as critical as they ought, and have omitted to prove satisfactorily that such cases should be referred to malarial poisoning.

**Diagnosis.**—It is often very difficult to diagnosticate a case of intermittent fever at the first visit, particularly in a place where malarial poisoning is infrequent. The history of the case is by no means always enough to put one on the right track; and a single examination of the patient may prove equally negative in its practical results, whether it is made during the febrile stage or in the interval. Continued observation, however, will almost always disclose the regularity of the febrile attacks, the splenic tumor, the characteristic complexion, and the herpes; and our diagnosis becomes evident. Still it is not very exceptional for an intermitting fever to be taken at first for an intermittent malarial one, while eventually some quite different disease is found to produce the symptom. Pyæmia may give rise to mistakes of this kind; also purulent phlebitis, acute ulcerative endocarditis, and even tuberculosis. We should be very cautious in making a hasty diagnosis of "irregular intermittent fever." Our own experience has taught us that almost invariably the case turns out to be something else. Where there is doubt we may, in addition to a careful consideration of all the symptoms and a thorough physical examination, be aided by the therapeutic action of quinine (*vide infra*). If a high fever of intermitting type is affected by large doses of quinine but temporarily if at all, then a diagnosis of malarial intermittent fever is rendered doubtful.

**Treatment.**—Malarial poisoning is one of the few diseases upon which we can make a direct attack with assured success. In quinine we possess a remedy which probably acts upon the very cause of the disease, and the therapeutic efficiency of which is undisputed. Quinine is therefore the sovereign remedy in all forms of malarial poisoning, and is often the only drug employed. In the mild cases, which are the only kind that occur among us, we do not usually give the remedy upon the instant that the patient comes under treatment. It is best to wait for one or two attacks, partly to make sure of our diagnosis, and partly to learn what the type of the fever is, whether quotidian, tertian, anticipating, or recurring at the same hour. And in most cases this delay works no harm to the patient. During the attack itself there is seldom any use in special treatment. Of course, the patient must stay in bed and be kept warm during the cold stage, and have lighter coverings during the hot stage. During the afebrile interval the patient may be up if he feels strong enough and is careful. Quinine is given about five or six hours before the next attack is due. It is best to administer one large dose of twenty to thirty grains (1.5–2 grm.), either in solution or in capsules of seven grains (0.50 grm.) each. If the quinine be given in powder or capsules, it is a good way to follow it with a few drops of muriatic acid, to promote its solution in the stomach. Often one large dose prevents the next attack. In other cases it does occur, but with less subjective disturbance, no chill, and more moderate fever. We must then give another large dose before the second attack is expected. If the attack does not take place, then we may give for several days quinine to the amount of eight grains (0.5 grm.) *per diem*. After all, relapses are possible, even at the end of several weeks; but they yield readily to quinine.

Judging from our own experience, conchicine is the only one of the other preparations of cinchona which is as efficient as quinine. It costs only half as much, and is prescribed in just the same way. A disadvantage is that it is more apt than quinine to excite vomiting. All the other preparations of Peruvian bark, such as chinoidine and cinchonine, are much more uncertain in their action.

In the treatment of pernicious intermittent fever, of the masked forms, of the remittent and continued fevers, and of malarial cachexia, the chief remedy is likewise quinine, given in sufficient doses. Baccelli has shown that sometimes in pernicious fever the direct injection of quinine into a vein may save life. In all cases of considerable duration it is also of the greatest importance to remove the patient from the malarial region, if it can possibly be done. This often proves to be the only way to avoid relapses and attain a perfect cure.

In cases of longer standing, quinine sometimes loses its power. Then we resort to arsenic. It is frequently employed in malarial cachexia and in intermittent neuralgia, either alone or combined with iron. We give gtt. v to viij of Fowler's solution two or three times a day in water. It is still better to give pills of arsenious acid containing gr.  $\frac{1}{80}$ – $\frac{1}{50}$  (0.002–0.003) and gradually increasing to a daily dose of gr.  $\frac{1}{8}$ – $\frac{1}{4}$  (0.010–0.012). It may be added that arsenic is also said to have a prophylactic virtue: a long-continued use of it is stated to render a person proof against malarial poisoning. It may also be mentioned that a favorite remedy for chronic malarial cachexia among the Italian peasants is a decoction of lemons. It is even highly praised by local physicians. A finely sliced lemon is put with three glassfuls of water and boiled down to one glassful. We will not speak of the numerous other remedies recommended, such as eucalyptus, piperine, pilocarpine, berberine, and many others, for they can be entirely dispensed with.

The management of the severe varieties of malarial disease involves symptomatic treatment as well as the administration of quinine. We can not enter into the particulars. In combating the grave, nervous, intestinal, pulmonary, and renal symptoms, the dropsy and the anæmia, the physician must conform to the general rules of treatment.

[There is nothing to be gained by allowing a patient to have an unnecessary chill. If there is a reasonable probability that his paroxysms are due to malaria, a prompt effort should be made to cut them short. Four hours is the shortest time that it is safe to allow for quinine by the stomach with probability that the expected chill will be prevented. The drug acts much more promptly when given hypodermically. The hydrobromate is preferred by some to the sulphate for subcutaneous use on account of the necessity of using acid to dissolve the latter, and the consequent risk of abscess. Such a risk should have no weight if the physician has any suspicion that he has to deal with the pernicious form of the disease. If the stomach is irritable, the remedy can be given by enema. Quinine can also be given by suppository, though it may thus produce some irritability of the rectum. But the impossibility of disguising the bitter taste of the remedy or of making children swallow capsules renders this a valuable means of treatment sometimes in infants and young children.

Warburg's tincture is an antiperiodic which does good service in cases which do not yield to the ordinary methods of treatment.

The hypodermic injection of pilocarpine is reported to abort an impending chill.

Some prefer divided and smaller to the single and large dose of quinine or one of its substitutes, a difference of view which is of minor importance.

In the remittent forms boldness in the use of quinine is required. Cinchonism should be induced as promptly as may be, and maintained to a mild degree for several days; the quantity of the drug can then be gradually diminished.

The treatment of the pernicious forms of periodic fever presents itself under three main heads:

1. The prevention of pernicious paroxysms.
2. The treatment of the paroxysm when present.
3. The prevention of a recurrence.

1. We have seen that very frequently the pernicious character is manifested after the occurrence of one or more mild attacks; consequently, in localities and seasons marked by the occurrence of grave cases it is an imperative duty to treat every mild case promptly and energetically, a course which unquestionably saves many a life.

2. The management of the paroxysm differs according to the form which it assumes; in other words, is largely symptomatic. Bemiss (Pepper's "System of Medicine") says: "The cure of a congestive chill is one of the most difficult problems the physician can possibly encounter." Heat externally, opium and chloroform by the mouth, and morphine and atropine subcutaneously, nutrition by the stomach or rectum, according to circumstances, and alcoholics if the action of the heart is feeble, are the measures of widest application.

Whatever the type of the attack, a weak heart calls for alcoholic stimulation. Cinchonism is always to be induced as rapidly as possible.

In the comatose form it is to be remembered that the cerebral and other nervous symptoms are not due to congestion, but probably to a combination of the malarial and secondary blood-poisons. To quote Bemiss again: "Efforts to nourish the patient must never be relaxed. One must see many of these cases before he can realize how often they recover from conditions apparently hopeless when promptly treated and properly nourished."

The hæmorrhagic form, like the others, demands cinchonism and careful nutrition, but also hæmostatics. Purgative doses of calomel are indicated in some cases of each form, but should not be given in a routine manner.

3. Prompt cinchonism is the chief means of attaining the third aim of treatment. Removal to a healthy locality should be secured if possible, and the general condition of the patient requires careful attention.

It remains to add that those going to a malarial region can often avoid contracting the disease by taking advice of a local physician as to hygienic precautions, and by moderate divided doses of quinine.]

---

## CHAPTER XV.

### TYPHO-MALARIAL FEVER.

[This is not a distinct disease, but expresses a combination in the same individual at the same time of the effects of the special poison causative of each affection. Typhoid being a continued fever, its complication with malaria results in a pyrexia of a remittent type. Typho-malarial fever occurs in malarial regions, especially in the Southern States, and may be seen in non-malarial regions in the persons of those in whom malaria, contracted elsewhere, is in a more or less active state.

The characteristic symptoms of the two diseases are intermingled, those of typhoid, the graver disease, usually predominating. The history of the case and careful observation of the symptoms will generally clear up any doubts felt as to the diagnosis in the early stages. It would naturally be supposed that the combined affections must produce an illness more severe in character and

more unfavorable as regards prognosis than belongs to simple typhoid. Such does not, however, seem to be the case. Woodward's statistics show that the mortality of uncomplicated typhoid was far greater among the white and colored troops alike during our late civil war than was the mortality of typho-malarial fever.

The treatment as regards the typhoid fever differs in no way from that suitable for cases of the ordinary affection; the periodic element demands the management appropriate to simple intermittent or remittent fever.]

## CHAPTER XVI.

### DENGUE.

[THIS affection has never appeared in Germany, and hence, doubtless, was omitted by the author. The name "dengue" is supposed to be a Spanish corruption of dandy, the term dandy fever having been applied to the disease by the West India negroes on account of the stiff carriage of those affected by it. Another name is "break-bone fever."

The disease generally appears in epidemics, and is almost exclusively confined to tropical and semi-tropical countries. In 1780 an epidemic supposed to be dengue prevailed in Philadelphia, and outbreaks have occurred repeatedly in the Southern States during this century. In 1880 Charleston, Savannah, New Orleans, and other Southern cities were visited by it. There are those who maintain that dengue and epidemic influenza are identical, a view which the facts do not seem to the editor to bear out.

**Etiology.**—As to the causation but little is known. Those who have had opportunities of studying the disease consider it both contagious and infectious, and the inference that it depends on a specific germ is readily suggested. It seems to prefer low lands along the sea-shore, and to be influenced by meteorological conditions in that it generally prevails during the summer and disappears as cold weather comes on. Neither age, sex, nor condition affords any protection from the disease; it was thought by Dickson that one attack generally confers immunity for life.

**Pathology.**—The disease is so rarely fatal that few opportunities have been afforded for its post-mortem study. So far as is known, it has no peculiar lesions. The prominence and the character of the muscle and joint pains have led some observers to think the affection related in some way to rheumatism.

**Symptoms and Course.**—The onset is usually sudden, but a pronounced chill is said never to occur. Prodromata similar to those of other infectious diseases are sometimes observed, but the first symptom is very often pain and stiffness in the muscles and joints, with frequent swelling of the latter. The large and small joints are equally affected, and the pain is increased by motion. With the pain there is a rise in temperature and in the frequency of the pulse. The pain is apt to increase during the first two or three days and disappear on the fifth, but irregular remissions are liable to occur. As the thermometer falls the pain and other symptoms diminish, but reappear in full force with any subsequent rise. During the later days of the disease a skin eruption appears on the upper part of the body, and in severe cases becomes general in about two days. This eruption is very variable in character; it may appear simply as an erythema, or simulate the eruptions of scarlet fever, rubeola, lichen, or urticaria; it is apt to be associated with well-marked heat and itching of the skin. In mild cases the eruption is evanes-

cent or absent. Swelling of the lymphatic glands is not uncommon; in severe cases the mucous membrane of the mouth, throat, and nose is reddened, and hæmorrhage from the outlets of the body has been observed. Pregnant women are apt to miscarry. Delirium is rare in adults, but common in children; the face is generally flushed, and the eyes are injected; the tongue becomes increasingly coated as the disease progresses, the appetite is lost, nausea is not uncommon, vomiting is rare. The bowels and the kidneys present no constant or distinctive symptoms.

In mild cases recovery is sometimes rapid; sometimes, and especially after severe cases, convalescence is very tedious, the muscular and articular pain and stiffness passing off gradually, and the glandular swelling lasting for weeks. Copious skin eruptions are followed by desquamation.

**Diagnosis and Prognosis.**—As to diagnosis there can seldom be any difficulty during the prevalence of an epidemic. The first cases are the only ones which are liable to be mistaken, and even their nature can not remain long in doubt. The prognosis is uniformly good.

**Treatment.**—We are acquainted with no agent capable of aborting or cutting short the disease; nor is there any known measure of prophylaxis except for an individual to keep away from those places in which the affection is known to prevail.

The treatment of the attack is simply symptomatic; notable pain calls for opium in some form. Quinine has not seemed to be of service. Debility following the attack demands suitable alimentation and tonics.]

## CHAPTER XVII.

### YELLOW FEVER.

[THIS disease is not a visitant of Germany, but its consideration can not be omitted from a text-book on the practice of medicine for use in America. In the following description the aim will be to bring out the more important features of the disease, while for fuller details the reader is referred to larger works and monographs.

**Ætiology.**—Yellow fever is an acute infectious disease, confined within certain geographical limits, and occurring chiefly in epidemics of greater or less extent. In certain localities, notably Havana and New Orleans, a season rarely passes without some sporadic cases. The influence of temperature is well established; the disease prevails, namely, during the summer or the warm season, and is abruptly arrested by one or two decided frosts; dampness is favorable to it. That it depends ultimately on a special cause and does not originate *de novo* are undisputed facts; but we still remain in ignorance as to the precise nature of this special cause. The poison appears to be more active at night than during the day, prefers low-lying districts, and in them hugs the ground to a certain extent. Bad sanitary conditions are most important accessory causes of the disease, furnishing the soil for the multiplication of the poison. There can be little doubt that, under the observance of strict personal and public cleanliness, yellow fever visitations might be made simply a matter of history. The transmission of the poison probably takes place solely through the atmospheric air, thus finding its way to the blood through the lungs; conclusive evidence is lacking that it gains entrance to the system through the alimentary canal. While the air is the medium of transmission, the distance to which the poison can be carried by the air alone is very short;

it can, however, be transported to an indefinite distance by fomites, especially if inclosed in trunks, packing-cases, letters, and the like. Its vitality may thus be maintained for very long periods. It is a remarkable fact that in large cities the infection may be of great virulence, but confined to a limited district or districts, by carefully shunning which unprotected persons are comparatively safe. An infected area is apt to extend itself, but the progress is slow, and is interrupted by streams of water, high walls, or simply streets.

That the disease is not, strictly speaking, contagious is the nearly unanimous opinion of those competent to form one. In other words, the poison is not thrown off in a matured state from the body of an individual suffering from the disease; but, after being so thrown off, remains in the atmosphere or lodges on solid bodies, and then undergoes changes which render it active for evil. One attack of the disease renders the system of that person insusceptible forever after; the natives of a yellow-fever district are far less liable to contract the disease than are those who move into the district from elsewhere; until these have passed through an attack they can not consider themselves as acclimated. The negro race is susceptible to the disease, though in a less degree than the whites, and in the colored the affection is far less fatal. Neither age nor sex has any special bearing on susceptibility. That fear, anxiety, worry, or anything which tends to depress the nervous system increases the individual liability is highly probable. The stage of incubation is very variable, ranging from one day to three weeks or even more.

**Pathological Anatomy.**—The disease involves no constant and peculiar lesions. In rapidly fatal cases, congestion and often hæmorrhage are found, especially in the nervous system, liver, kidneys, and digestive tract. In fatal cases of longer duration more or less parenchymatous degeneration is found. A fatty degeneration of the liver is quite common, and imparts a yellow coloration to the organ, giving rise to the terms *café au lait*, or box-wood liver. Jaundice of the skin and tissues generally is also observable after death, and depends upon causes in no way connected with mechanical obstruction to the flow of bile into the intestine during life. Splenic enlargement is conspicuous by its absence.

**Course and Symptoms.**—The onset of the disease is generally sudden, but may be preceded for a few days by malaise and other signs of general constitutional disturbance; the initial chill is seldom severe, reaction following soon and the thermometer rising to 102°-105°; hyperpyrexia is rare. The pulse-rate does not increase proportionately with the fever. The face becomes flushed and the eyes injected and watery; headache and pain in the back are early and usually very prominent symptoms. The bowels are confined; the tongue is apt to be clean if it was so before the disease came on; the stomach is usually somewhat irritable, and there may be vomiting; moderate epigastric tenderness is common; the mind remains clear, as a rule, but delirium is not very uncommon, and in children a convulsion may usher in the attack as in other acute infectious diseases; the condition of the urine is at first not remarkable, but albumen may soon appear. This hot or febrile stage may last from twelve hours to several days. The pulse generally declines in frequency before the disease has reached its maximum. As the fever disappears the other symptoms vanish also, and the second, or "stage of calm," begins. From this point recovery may be rapid and uninterrupted, the whole disease consisting of but a single febrile paroxysm of greater or less intensity and of short duration.

In grave cases, and gravity is often foreshadowed in the first stage by marked capillary congestion of the surface of the body irrespective of the intensity of the other symptoms, and after a stage of calm lasting for some hours, but rarely exceeding twenty-four, more distinctive symptoms appear. The pulse is very com-

pressible, the surface of the body is cool, vomiting occurs or becomes more prominent, and hæmorrhage is now apt to take place. The escape of blood into the stomach, its retention and the changes which it there undergoes, and its subsequent expulsion, explain the dreaded and characteristic symptom known as "black vomit." Tarry stools sometimes are observed. Hæmorrhage elsewhere is also common, occurring from the gums, the nose, eyes, uterus, kidneys, into the skin, etc. Albuminuria with casts is very common. Jaundice, sometimes of a lemon-yellow hue, comes on, and is rarely lacking in severe cases. From this symptom the name of the disease is derived.

In cases marked by more or less complete suppression of urine, coma and convulsions, probably largely uræmic, come on. Some severe cases are of the "walking" type, the patients going about while the malady is far advanced, or even up to the time of death. As a rule, however, muscular prostration is marked.

If the disease does not prove fatal in this third stage, convalescence comes on more or less gradually, and is followed by complete recovery; relapses, however, occasionally occur.

The duration of the affection is variable but, on the whole, short, usually being less than a week.

**Diagnosis.**—In mild cases the symptoms are not distinctive, and the diagnosis at the commencement of an epidemic is not likely to be reached except by an experienced observer, and even by him more or less conjecturally. During an epidemic the severe lumbar pain, the headache, the suffusion of the eyes, and the moderate gastric irritability, are all-sufficient for diagnostic purposes. Severe cases are also marked by capillary congestion of the surface of the body, and the third stage with the black vomit, hæmorrhage, jaundice, slow pulse, scanty urine, and prostration is characteristic. Of course, all the above symptoms are not present in every case. The only disease which can well give rise to confusion is remittent fever with jaundice. This affection has a different temperature curve, is not confined to the yellow-fever zone, is controlled by quinine, and is not accompanied by black vomit.

**Prognosis.**—This varies in any given locality with the character of the prevalent epidemic. The death-rate is sometimes very high, sometimes moderate; it is greater in hospital than in private practice.

In the first stage of the disease the chief element in the formation of the prognosis seems to be the presence of marked and general capillary congestion of the skin, a symptom which foretells a severe attack. The absence of this symptom is rather less important than its presence. Cases may turn out to be severe in which it is lacking. The frequent deceptiveness of the stage of calm is to be remembered.

Yellowness, black vomit, and suppression of urine are symptoms denoting the greatest gravity, but do not justify the complete abandonment of hope.

**Treatment.**—There are no means in our power of aborting the disease. Prevention is to be attained by cleanliness in its large sense, and by careful quarantine against things rather than persons. Individuals from infected localities may safely be admitted into non-infected localities, provided that they and their clothing and effects are thoroughly disinfected. Merchandise, the mails, and the like, must be excluded or disinfected. So also vessels and all other means of communication.

The earlier proper treatment can be instituted, the better. Absolute rest and good ventilation are the first requisites. Emetics and cathartics are not indicated by the disease itself; the condition of the stomach and bowels should be inquired into, and indigestible food or an accumulation of fæces should be removed if present. A hot mustard foot-bath early in the attack is useful. For the lumbar

pains, opium or morphine are indicated. Sinapisms, or other similar external counter-irritants, with ice internally, and hydrocyanic acid or chloroform, are serviceable against gastric irritability. High fever is to be combated by cold spongings, the wet pack, and the cold bath. For hæmorrhage, styptic remedies may be used, though it is doubtful whether, when given internally, they are really of much benefit. Of course, no medication is to be resorted to which is likely to heighten a tendency to emesis.

Suppression of urine is to be met by dry cups to the loins, diuretic remedies internally if the condition of the stomach allows, or the hot-air bath. The results of pilocarpine are disappointing according to Bemiss, who states that he has seen good effects from large enemata of water, preferably cold, if there be notable fever in these cases. Prostration is an indication for the use of alcoholic stimulants, among which iceed dry champagne ranks high. It will be seen that the treatment is entirely symptomatic. The disease is self-limited, has a short course, and the patient will recover if he can be kept alive until the poison is exhausted. During the attack and until convalescence is thoroughly established the management of the diet is all-important. Small quantities of the most easily assimilable food may be given at short intervals if they are tolerated by the stomach; if not, alimentation must be by the rectum, and the lower bowel in this disease is generally in a fair condition for this method of nutrition.

Courage and hopefulness on the part of the physician may do much good, and the services of a skillful and experienced nurse are of the utmost importance. I am told that in New Orleans, and perhaps elsewhere, it is customary, for those who are not protected and can afford this course, to secure in advance a nurse as soon as an epidemic breaks out. They then take to their beds at the first sign of illness.]

## CHAPTER XVIII.

### EPIDEMIC CEREBRO-SPINAL MENINGITIS.

(*Spotted Fever. Cerebro-spinal Fever.*)

**Ætiology.**—The epidemic form of cerebro-spinal meningitis has been known only since the beginning of this century. The first epidemics were observed in southern France and in Geneva. Smaller ones occurred in Germany in 1822 and 1853; but it was not till 1863 that the disease became at all frequent among us. Since that date there have been more or less extensive epidemics almost every year. The southern and central portions of Germany are particularly liable to them. Sporadic cases may occur at any time.

Most of the epidemics appear in the winter and spring. We do not know any particular factors which promote the disease. It often seems to be decidedly endemic. Barracks, work-houses, and the like have been marked by tolerably extensive epidemics. Whether the disease can be carried by patients to places previously free from it is still uncertain. It is not directly contagious. Children and young adults are the most frequent victims; but now and then elderly persons are attacked. Sex can not be shown to have much influence.

That the disease is infectious is clearly shown not only by its epidemic and endemic character, but by its whole course. The peculiar pathogenic organisms and the manner of infection have not yet, however, been ascertained. It is an interesting fact that Fränkel's pneumonia bacilli have been recently several times detected in the purulent exudation upon the meninges, so that some investigators have suggested that croupous pneumonia and epidemic meningitis may

be closely related from an ætiological standpoint, even if they are not actually two forms of a single disease. The author can not as yet wholly accept this view. It is indeed certain that the pneumonia bacilli may sometimes secondarily reach the meninges and here excite a purulent suppuration ("pneumatic meningitis," that is, metastatic meningitis complicating pneumonia); nor is it impossible that the pneumonia bacilli sometimes, and particularly at the time of an epidemic of pneumonia, do enter directly into the meninges and occasion a meningitis; but for the genuine epidemic meningitis we must seek some special pathogenic cause. Otherwise it would be impossible to explain why the same germs should sometimes find their way exclusively into the lungs and at other times and in other localities invariably into the cerebral meninges.

With regard to the gate of entrance of infection in primary epidemic meningitis, perhaps the specific poison may enter through the nostrils and the cribriform plate to the otherwise so well protected envelopes of the central nervous system.

[Sanitary conditions seem to play a less important rôle in this than in many other infectious diseases. During the epidemic which visited New England in 1873 the writer was interne at the Massachusetts General Hospital, and there saw a number of cases. The disease was also prevalent among horses at the same time, and it is curious to note that a like association of the affection in men and animals was observed in Vermont in 1811, and in New York city in 1871. During the year 1873, 216 deaths were returned as due to this malady in the city of Boston.]

**Pathological Anatomy.**—The autopsy discloses an acute purulent cerebro-spinal leptomeningitis. It is only in rapidly fatal cases that slight and incipient lesions have been met with. As a rule, the extent and intensity of the objective lesions correspond to the severity of the symptoms. In the brain the purulent inflammation attacks the convexity as well as the base. It is usually most marked along the larger blood-vessels and in the fissures of the cortex. Of the spinal cord the posterior surface suffers most. Frequently the lumbar portion is more affected than the parts above. It is, however, exceptional for the disease to be limited to the meninges; it is prone to extend into the underlying parenchyma. The microscope reveals clumps of pus-corpuscles about the blood-vessels, where they penetrate into the tissues, and not infrequently there are numerous centers of genuine encephalitis. These latter may be visible to the naked eye. Exceptionally there may even be cerebral abscesses of considerable size. The vessels are distended with blood, clear into the central ganglia, and ecchymoses are frequent. The cerebral ventricles are usually enlarged, and filled with a cloudy serum, or even with pus. It is plain that these lesions of the cerebro-spinal parenchyma greatly modify the clinical picture, and that they must frequently have more to do with the severity of the symptoms than has the leptomeningitis itself.

**Clinical History.**—Prodromata are relatively rare, and if present they are not severe, being confined to general malaise, with slight headache, and pain in the limbs. Usually the disease begins rather suddenly; there is intense headache, often mainly felt in the back of the head, pain and stiffness in the back of the neck, and great general discomfort. It is not rare for vomiting to occur at first. Very often there are among the early symptoms such important mental disturbances as stupor or delirium. There is usually fever from the first. An initial rigor may occur, but it is not the rule.

The intensity of these first symptoms is uncertain. Subsequently to them the course of the disease may vary greatly. First there are very acute, violent forms, termed "explosive" (*meningitis cerebro-spinalis siderans, méningite foudroyante*), where the cerebral symptoms are very severe, and the patient survives only a few days or even hours. Again, there are abortive cases. These

begin with equally threatening symptoms, but after a few days completely recover with remarkable rapidity. The majority of cases last about two to four weeks. In severe cases death may come as early as the first week. The disease is often protracted to six or eight weeks' duration, or even longer, and may end in death after all. Cases that last a good while sometimes exhibit a remarkably intermittent character. Finally, the number of mild cases is not small in which none of the symptoms are very pronounced, and recovery is relatively early.

The symptoms of the disease may be divided into (1) the severe general symptoms, referable to the brain and spinal cord; (2) the more localized, nervous symptoms; and (3) the results of the constitutional infection, including fever and diseases localized in other parts of the body.

1. Among the less definite cerebral symptoms headache is important. It is usually terribly severe. It is chiefly occipital, but sometimes is frontal or temporal. Like most of the symptoms of meningitis, the headache undergoes very frequent changes in intensity during the course of the disease. For a time it may remit, only to recur with fresh severity. Marked vertigo and a sense of fullness in the head may accompany it.

The pain in the head is re-enforced by intense pain in the nape of the neck and back, due to the spinal meningitis. There is almost always considerable tenderness along the whole spinal column. The erector spinae is contracted, making the back straight and rigid, or even producing opisthotonos; and the head is bent backward by the reflex contraction of the muscles in the back of the neck.

In most of the severe cases intelligence is blunted; we find all degrees of disturbance, from slight drowsiness to delirium on the one hand, or deep coma on the other. These symptoms likewise may undergo frequent variation in their intensity. General convulsions occur in very severe cases alone, and are of evil omen.

The vomiting is also to be regarded as of cerebral origin. It frequently is an early symptom, but may be deferred.

2. Symptoms referable to the individual cerebral nerves are manifold and variable. The most frequent disturbances are in the nerves that supply the motores oculi. They include strabismus; nystagmus, or slow movements independent of volition; unilateral or bilateral ptosis; slow reaction of the pupils, or inequality of them, or myosis or mydriasis. In the area of distribution of the facial there is often a noticeable contraction of the muscles, giving the face a peculiar, painfully distorted look. Trismus, or tetanus of the masseters, is rare, and usually a bad sign.

Disturbance of the nerves of special sense is frequent. Deafness may be due to the stupor, but is often the result of an extension of the inflammation to the acoustic nerve. The purulent inflammation may be propagated as far as the labyrinth, or even into the middle ear. Tinnitus aurium is also frequent. Disturbances of vision are far less frequently observed, but optic neuritis has been repeatedly found by the ophthalmoscope. Severe purulent irido-choroiditis has been also observed. It is probably due to extension of the inflammation along the sheath of the optic nerve. Conjunctivitis and keratitis sometimes occur; but they are probably caused by external injuries rendered possible by the imperfect closure of the lids, or the diminished sensitiveness of the parts. We have several times found the sense of smell diminished.

Disturbances in the area of distribution of the spinal nerves are, on the whole, less frequent. The only one of value in diagnosis is the cutaneous hyperaesthesia. It is apt to be particularly severe in the extremities, and it may be so extreme that the light touch of a finger or a needle causes great pain. Sometimes there is a slight twitching in the muscles of the extremities. This has, however, no special

significance. There is often rigidity and stiffness of the muscles. Kernig has called attention to the frequent appearance of flexure contractions in the legs, and sometimes also in the arms, if the patients are caused to sit up or if the thigh is passively bent upon the trunk. As might be expected, there is no invariable rule about the reflexes. The cutaneous reflexes are usually well marked, and the tendon reflexes may be; but in some cases we have found the tendon reflexes markedly diminished or even abolished. Such a condition is probably due to some lesion of the fibers of the posterior nerve-roots.

All of the nervous symptoms above enumerated result from one of two causes—either the roots of the nerves are affected by the purulent exudation, or the inflammation extends inward to the central organs themselves. This extension is the explanation also of other symptoms sometimes observed—viz., hemiplegia, paraplegia, partial convulsions, and aphasia.

3. In addition to all these nervous disturbances, we see also symptoms referable to other parts of the body. Of this class there is one cutaneous affection which is a very valuable aid to diagnosis. Herpes labialis or herpes facialis is apt to appear soon after the beginning of the meningitis. It is seen in more than half the cases, and as frequently in severe as in mild attacks. Other eruptions occur now and then—e. g., roseola, urticaria, or petechiae. Sometimes they are so symmetrically distributed upon the two halves of the body as to suggest the idea of a nervous origin.

The digestive system seldom displays severe symptoms beyond the vomiting already mentioned. Anorexia and constipation are, indeed, usually present, as in many grave diseases. We have seen mild dysentery a few times. Now and then a slight jaundice has been noticed. The spleen is often somewhat swollen, but very rarely attains great size.

Swelling of the joints has been observed quite often; it is much more frequent in some epidemics than in others. The enlargement may be an early or a later symptom. It does not usually prove to be of grave omen.

The urinary apparatus is seldom affected. The urine may contain some albumen and a few casts. Polyuria is an interesting symptom, probably of nervous origin. It is more apt to occur in the latter part of the disease. In a number of cases sugar has been found in the urine. Cystitis is a secondary disorder which is not very rare, particularly in severe cases where the catheter has been used.

Pulmonary and bronchial symptoms are likewise secondary. They occur very often in bad cases. It is evident how easily the stupor of the patient may lead to the inhalation of solid matter, with consequent bronchitis and lobular pneumonia.

Lesions of the circulatory system are rare. Acute endocarditis has been observed only a few times. The pulse is usually somewhat accelerated, seldom rendered slower. Very frequently the pulse-rate is remarkably variable, undoubtedly because of variation in the supply of nervous force. Slight irregularities in the pulse are also common.

4. The fever in epidemic meningitis conforms to no single type. It does not correspond at all to the severity of the other symptoms; the worst cases may run their course with little or no fever. In most cases the fever has irregular remissions. It seldom exceeds 104° (40° C.). Sometimes the fever exhibits a decidedly intermittent character. It is in these cases particularly that we find the variation in the intensity of all the symptoms of which mention has been made repeatedly. The variations in the temperature do not, however, always run parallel with the changes in the other symptoms. In mild cases the fever is usually moderate and brief. The abortive attacks may present high temperatures at first, but these quickly abate. In case of a fatal issue there is sometimes hyperpyrexia before

death, reaching 108° to 109° (42°-43° C.). In the severer but not fatal cases the fever declines slowly but irregularly. The fever may be over, long before the other symptoms disappear.

It is impossible to portray all the forms, symptoms, and courses the disease may have. The chief forms have been already mentioned; but in reality these are only types which run into one another without sharply defined border-lines. It is in itself a characteristic of epidemic meningitis that most of the more tedious cases have a variable, uncertain course. We may even meet with a complete intermission of all the symptoms, lasting for quite a while, so that the return of the trouble may fairly be called a relapse.

**Sequelæ** are not rare after severe cases. Persistent deafness is the most frequent. It results from the complications, already mentioned, which affect the labyrinth and the middle ear. Little children may become deaf and dumb. Again, vision may be deranged, because of retinitis, atrophy of the optic nerve, or corneal opacities, etc. It is not very rare for meningitis to leave grave nervous disorders behind it. These are frequently the symptoms of a chronic hydrocephalus. We may observe headache, sudden unconsciousness, or even convulsions, mental impairment, and weakness of the extremities. Or there may be localized disturbances due to permanent injury of limited portions of the brain or spinal cord, such as hemiplegia, paraplegia, and aphasia. From many of these conditions there may be a gradual recovery, but others prove incurable.

The **diagnosis** of cerebro-spinal meningitis is not difficult in a well-developed case, particularly if the prevalence of an epidemic puts us in mind of the disease. Diagnosis is more difficult in sporadic cases, and most of all when the patient does not come under observation till he is very ill and when we can not obtain the previous history. Important factors are the abrupt onset, the speedy appearance of grave cerebral symptoms, the characteristic headache and pain in the back, the stiffness of the neck, and the herpes labialis.

If we find evident symptoms of meningitis, we have still to decide whether the case is one of primary epidemic disease, or secondary, perhaps due to extension from some other part. Bearing this last possibility in mind, we should examine the ears carefully; for, as is well known, chronic otitis media may set up a purulent meningitis. Again, it may be very difficult to exclude a tubercular meningitis. Here we should consider other conditions that might render tuberculosis probable, such as the general condition of the patient, heredity, previous pleurisy, the results of thoracic examination, or scrofulous disease of the bones or joints. The existence of herpes points toward epidemic meningitis, for it is exceptional in the other forms of the disease. It is sometimes difficult to distinguish between meningitis and severe cases of other acute infectious diseases—e. g., typhoid fever and septic diseases. Here we must weigh all the circumstances carefully.

This is a good opportunity to mention the secondary meningitis which is said to occur with relative frequency just at the time of an epidemic. The combination of croupous pneumonia (*q. v.*) with purulent meningitis has been repeatedly observed. Still, it is not easy to determine whether the cause of this secondary meningitis is actually identical with that of the epidemic form (*vide supra*). In other acute diseases, like typhoid and articular rheumatism, when they occur at the time of an epidemic, the "tendency to meningitis" is potent enough to make meningeal symptoms more frequent than usual. It has not been clearly demonstrated, however, that this fact is actually due to the epidemic meningitis.

The **prognosis** depends chiefly upon the severity of the cerebral symptoms. Yet we should be guarded in our utterances, even when the case seems mild, or has apparently made the first steps toward convalescence. The disease sometimes

changes for the worse at a late period. In general the mortality is about thirty to forty per cent. Probably this estimate does not take into account many very mild cases.

**Treatment** is purely symptomatic. There is no specific for meningitis. A valuable remedy is cold applications. Ice-bags are placed upon the head, and, if possible, along the spine. There are long and narrow rubber ones for the latter purpose. These applications are borne well by most patients and afford decided relief. The local abstraction of blood has also an undeniably beneficial influence, however difficult this may be to explain. Leeches are put behind the ears, and cupping-glasses on the back of the neck and along the spine. Mercurial ointment is often rubbed in, not only locally but also in the same way as in treating syphilis. Its use is doubtful. The narcotics are of great value. The best is morphine given subcutaneously. It lessens the pain, and often affords the uneasy and delirious patient rest and sleep. Chloral and bromide of potash may also be employed. Iodide of potash is often given internally, to the amount of twenty to thirty grains (grm. 1.5-2) in a day. It is said to act as an "absorbent," particularly in tedious cases.

The fever hardly ever requires special treatment. If the fever intermits, still quinine exerts no permanent influence. Antipyrine is better borne, and it also sometimes relieves the nervous symptoms. Bathing involves manipulations which most patients find unpleasant and painful, so that baths can seldom be employed, at least in the more acute stages of the disease. Later, warm baths are often beneficial. Local complications—e. g., affecting the eye or the ear—require special treatment. The swelling of the joints which sometimes occurs we have thought to be somewhat relieved by salicylic acid.

## CHAPTER XIX.

### SEPTIC AND PYÆMIC DISEASES.

(*Spontaneous Septicæmia.*)

THE septic and pyæmic processes which follow serious injuries or operations belong to surgery; but analogous diseases occur in persons who are apparently in perfect condition. They take the form of an extremely severe acute infectious disease, usually fatal. There is often the greatest difficulty in diagnosing these cases during life. Probably the most intelligible way in which to present these interesting and clinically important diseases will be to start with their pathology, and subsequently to speak of their ætiology and clinical history.

**Pathological Anatomy and Ætiology.**—The most striking features at the autopsy of such cases is that there is never found a lesion of one organ exclusively. Several, or it may be almost all of the organs, exhibit numerous limited foci of disease. The lesions sometimes consist for the most part of multiple abscesses, sometimes of numerous ecchymoses, and sometimes of combinations of the two. The abscesses are found chiefly in the lungs, kidneys, liver, spleen, muscles, heart, brain, and thyroid gland. Quite extensive purulent inflammation is also found. This attacks the joints by preference, but also the pleura and meninges and the eye, where it causes purulent choroiditis, panophthalmitis, and purulent degeneration of the vitreous. The ecchymoses are most frequent upon the surface of the body, the serous membranes (e. g., the pericardium and the pleura), the retina, and conjunctiva; and also in the brain and the pelvis of the kidney. Besides these multiple abscesses and ecchymoses, there is frequently another disorder, which seems to be

the very focus of the disease, viz., acute ulcerative endocarditis (cf. the appropriate chapter). This usually attacks the mitral valve, more rarely the valves of the aorta, and quite exceptionally the valves of the right side of the heart. Finally come a number of changes common to all severe constitutional infectious diseases—acute splenic tumor, "cloudy swelling" of the liver and kidneys, a dryness and dark-red color of the muscles, etc.

A glance over this pathological picture makes us feel certain that some pernicious agency pervades the whole system. And this factor we can, in all cases, demonstrate beyond a doubt to be bacteria. In this way is established the etiological unity of many forms of disease which were once regarded as quite distinct because of their different localizations, for instance, endocarditis, osteomyelitis, and phlegmon. These micro-organisms are found not only in the exudations due to the endocarditis, but also in the midst of numerous small foci of inflammation situated in the internal organs, where they usually completely fill some little blood-vessel with what is called an embolus of micrococci. The large foci of inflammation visible to the naked eye are mostly purulent—i. e., are abscesses. Most of the internal viscera also contain very minute foci, devoid of nuclei, and in a state of "coagulation-necrosis." These are visible through the microscope alone. They may be combined with ecchymoses, and usually they are when seen already surrounded by a zone of secondary inflammation. This necrosis of tissue seems to be the first thing which the bacteria accomplish. The cutaneous, retinal, and other ecchymoses are frequently attended by the presence of bacteria; but this relation is not always observed. The relations here are perplexed, because we have to consider not merely the especial peculiarities of the different forms of bacteria (*vide infra*), but also the direct effect of the micro-organisms themselves in distinction from the chemical poisons ("toxines") generated by the same. The formation of pus itself seems to be invariably dependent upon the presence of bacteria, while on the other hand the hæmorrhages may apparently follow purely chemical intoxication. The prevailing custom is to term the cases of multiple abscess pyæmic, and those where there are merely ecchymoses and foci of inflammation, without actual suppuration, septic in the narrower sense of the term. But as the two forms are often combined, we also speak of a "septicopyæmia." From a strictly ætiological standpoint it is not probable that all the septicopyæmic diseases are to be regarded as identical. It is certain that in most cases of pyæmia the *Streptococcus pyogenes* may be regarded as the special cause of the disease. In less frequent instances it is the *Staphylococcus pyogenes aureus* which enters into the general circulation and produces pyæmic conditions, and it is probable that still other varieties of bacteria are sometimes concerned. Whether in human beings specific septicæmic bacteria are ever present is still unsettled. The general opinion is, as already mentioned, that septicæmia in the narrower acceptation of the word corresponds more to an intoxication of the body, whether due to the toxines of putrefaction or to those generated by the pyogenic bacteria. Brieger's admirable investigations have shown that the *Streptococcus pyogenes* produces large amounts of trimethylamin and the staphylococcus large amounts of ammonia.

Of course the bacteria, which are the real cause of the disease, must have penetrated into the body from the external world. In fact, careful search will reveal, in the great majority of cases, the place of infection. It follows that the idea of an actual "spontaneous" pyæmia, arising within the system, must be entirely abandoned.

The factors which most frequently excite septic or pyæmic infection are as follow: 1. The condition subsequent to labor or abortion, particularly the latter. The raw surface of the uterus furnishes ingress to the septic poison. Nor is it by any means the invariable rule that the uterus and its appendages should exhibit

any considerable pathological change as a result of this absorption. We do find, often enough, diphtheritic and gangrenous inflammation at the place where the placenta was inserted, or purulent thrombi in the veins of the uterus and of the pelvis; but in other cases the uterus is merely a gate of entrance for the poison, remaining itself unharmed. 2. The septic poison may also be absorbed through slight abrasions of the skin, etc.; and these may be almost completely healed by the time the severe symptoms of disease are developed. Bed-sores belong in this category. 3. Ulcers of the mucous membranes may give rise to infection. This is the explanation of those cases of sepsis which complicate typhoid fever, dysentery, or diphtheria. 4. Lastly, we sometimes find no other source for the pyæmia than a suppurating disease of the bones, joints, or other parts, previously existing. The above enumeration by no means exhausts all the possibilities. Still, it will be found to explain most cases. The more minutely we search for a possible place of entrance for the septic virus, the less often we fail to find one. [The editor has seen two clear cases, one confirmed by autopsy, of general septic infection and malignant endocarditis as a sequel of gonorrhœa.]

When the poison has once made its way into the system, it can be disseminated through various channels. It may be carried by the lymphatics into the general circulation. A purulent phlebitis may be excited at the point of infection; and this in turn may excite, chiefly through embolism, secondary abscesses. These abscesses occur first in the lungs and then in other organs. It seems to be possible for a purulent phlebitis to arise in a vein remote from the place of infection. The valves of the heart often greatly promote the dissemination of the septic matter. The virus is prone to fasten upon them, probably purely from mechanical causes. This results in acute endocarditis. In such a case we must regard the endocarditis merely as one of the symptoms of the universal septic infection. But the valves are a fertile soil for the propagation of the poison, and emboli carry away from them a great deal of infectious matter to the various organs; and so the acute endocarditis becomes in many instances the central factor in the whole process. Yet in other cases there is little or no endocarditis.

**Clinical History.**—It is our intention to discuss below those cases chiefly which are of interest to the physician rather than the surgeon—i. e., where the septico-pyæmia is an apparently primary, acute, and grave disease. Many of the essential traits of this type of disease are identical with those of the pyæmia which complicates the effects of serious wounds or the inflammation subsequent to childbirth; but it is precisely because no cause at all presents itself that many cases of the disease seem so obscure, and are so often wrongly diagnosticated. Besides, the patient may be very ill indeed before the physician sees him; and this adds greatly to the difficulties of a correct diagnosis.

The beginning of the disease is usually rather abrupt. An apparently healthy person is attacked with febrile symptoms, headache, and "rheumatic" pains in the muscles, joints, and loins. There may also be gastro-intestinal symptoms of considerable severity, including vomiting and diarrhœa. Usually the patient feels ill enough to take speedily to his bed. The symptoms now increase rapidly, and develop into a severe illness which may resemble either a bad case of typhoid fever or miliary tuberculosis. Or the cerebral symptoms, such as headache, stupor, and delirium, may become so prominent that the attack seems like meningitis. If the trouble in the joints (*vide infra*) predominates and there are signs of endocarditis, the disease may at first be taken for a violent attack of acute articular rheumatism.

Taking up the separate symptoms, we shall first name those which belong to every severe acute infectious disease and have nothing characteristic about them. In this list belong the general prostration, the anorexia, the mental disturbance,

the stupor and delirium, the headache, the subjective symptoms of fever, the dryness of the tongue, and finally the acute splenic tumor which can often be made out. There are, however, other and more characteristic symptoms; and it is chiefly upon these that the diagnosis rests, provided we can make one at all. These are:

1. *The Course of the Fever.*—In many cases it must be confessed that this is not at all characteristic. It may even be so like that of typhoid fever as to lead to a wrong diagnosis. But in other cases the temperature-curve does aid us greatly, viz., when it represents an intermitting fever with marked elevations, reaching 106° (41° C.) and higher, and often accompanied by a chill, and with subsequent deep depressions. The curve may thus come to resemble closely that of a quotidian or even tertian intermittent fever. Sometimes, again, the course of the fever is made up of similar paroxysmal elevations, separated by periods of ordinary remitting fever.

2. *Cutaneous Symptoms.*—These are very frequent, and a great aid to diagnosis. The hæmorrhages into the skin are of chief importance. They may be either punctiform petechiæ or more extensive ecchymoses. If petechiæ, it may be very hard to distinguish between sepsis and the purpura of small-pox (*q. v.*). Of other cutaneous appearances, the first in relative frequency is an erythema resembling scarlatina. It is not improbable, as we have already said, that many cases which have been described as severe scarlet fever occurring during childhood were in reality septic disease. Roseola, wheals, pustulous eruptions, herpes, and phlegmonous inflammations have also been observed.

3. *Ocular Disturbances.*—The purulent inflammations of the eye, which are probably of embolic origin and which may develop into diffuse septic panophthalmitis, have been known for some time. Lately, Litten and others have called attention to more minute changes in the fundus of the eye. These are revealed through the ophthalmoscope, and have great diagnostic value. Chief among them is retinal hæmorrhage, which is sometimes accompanied by a white spot in the center, corresponding to a necrosis of the retina in that place; but there may be similar white spots without hæmorrhage.

4. *Circulatory Disturbances.*—An ability to recognize the cardiac lesions would be very desirable; but often this is impossible before death. The pulse is indeed frequently much accelerated and irregular; but such signs alone lead to no definite conclusion. Endocardial murmurs are often wanting, even in cases where the autopsy discloses abundant exudation and ulcers upon the valves. Still, in some cases of this sort we have found the heart-sounds noticeably deficient in clearness. Sometimes we hear blowing sounds, which might, however, quite naturally be regarded as functional. There are no noticeable changes in the blood. Bacteria have not yet been demonstrated in the blood of the patient during life. Sometimes a distinct, though moderate, increase in the number of white blood-corpuscles is observed.

5. The grave cerebral symptoms are for the most part quite analogous to those in other severe acute infectious diseases. They may be present, and yet no marked objective lesions may be found after death. In other cases they have an anatomical basis—in purulent meningitis, hæmorrhagic pachymeningitis, cerebral hæmorrhage, or abscess. These conditions, just enumerated, may excite localized cerebral symptoms, e. g., hemiplegia.

6. Affections of the joints are comparatively frequent, and of great value in diagnosis. We may find purulent inflammation, or even periarticular abscesses. If they appear early in the attack, they may, as we have said, lead to an erroneous diagnosis of acute articular rheumatism. Suppurative processes affecting the periosteum and the marrow of the bones not infrequently accompany the joint

affections. If there is decided suppuration in the bones we speak of an acute osteomyelitis, especially in the lower extremities. This condition is almost always occasioned by the staphylococcus aureus. In earlier times such cases were termed bone-typhoid. Finally, abscesses in the muscles are not uncommon.

7. Renal changes are frequent, but seldom produce striking clinical symptoms, or prove of value in diagnosis. The urine often contains a moderate amount of blood and albumen; but yet it may not be essentially altered in cases where the autopsy discloses extensive renal abscesses or ecchymoses, or hæmorrhages into the mucous membrane of the pelvis. In other cases, however, an acute septic nephritis is conjoined with the infarctions and abscesses, and then the urine exhibits all the characteristics of acute Bright's disease, having a large amount of albumen, red and white blood-corpuscles, epithelium, and casts.

8. The pulmonary symptoms are in part secondary. Bronchitis and lobular pneumonia develop as in all other severe constitutional diseases. The pulmonary abscesses of themselves give rise usually to no objective symptoms—or, at most, to a marked dyspnoea, out of all proportion to the scanty physical signs. Empyema is a not infrequent result of infection of the pleura, due to the foci of disease which are situated upon the outer surface of the lungs. If the aspirating-needle shows the actual existence of empyema, this fact may make the diagnosis of the constitutional disease much easier.

9. Of the abdominal symptoms we have already mentioned the acute splenic tumor. It is almost impossible to diagnosticate infarctions and abscesses in the spleen. If the spleen is enlarged and noticeably painful, we may suspect their existence. There are sometimes quite severe intestinal symptoms, such as a profuse "septic diarrhoea," in cases where the autopsy does not show any particularly grave lesions. Still intestinal ecchymoses and intestinal diphtheria have sometimes been observed. We should mention that often the skin has a faint jaundiced hue. This is sometimes the result of duodenal catarrh, but perhaps it is at other times hæmatogenous.

**Course of the Disease and Prognosis.**—The entire course of a septic case may be comprised within a few days, for a severe attack is always thus quickly terminated by death. Protracted cases are also seen, where the sufferings last one to two weeks, or even longer; but in these, again, the end is almost invariably unfavorable. It is not impossible that there are milder and curable forms. Our acquaintance with these last is, however, so slight that we can not state any particulars about them.

**Diagnosis.**—It is self-evident that a disease which combines symptoms so manifold and so ambiguous must be very difficult to recognize. We will recapitulate the chief diseases to be excluded. A case may greatly resemble typhoid fever when there is persistent prostration, diarrhoea, an eruption like roseola, and an enlarged spleen. In discriminating, we should consider with great care the possible ætiology—e. g., external injuries; and we should look for septic retinitis, swelling of the joints, cutaneous ecchymoses, and an intermitting form of fever. It is all the more possible for the disease to resemble meningitis, because, as we have said, meningeal disturbance may be one of the symptoms of the sepsis and color the whole picture. Here the symptoms of septic poisoning already mentioned would be of some value in diagnosis, and the physical signs of endocarditis or of a greatly enlarged spleen would be worth still more. There may be equal difficulty in the differential diagnosis between acute sepsis and acute miliary tuberculosis. Here we should consider carefully each separate symptom, and, above all, the ætiology, searching for something that would explain the occurrence of sepsis on the one hand, or of acute miliary tuberculosis (*q. v.*) on the other. If we found miliary tubercles in the choroid by means of the ophthalmoscope,

or tubercle bacilli in the blood, all doubt would vanish. At the beginning of a septic attack the rigors may arouse suspicions of intermittent fever. Usually the early appearance of other symptoms corrects this idea; but, if not, the powerlessness of quinine will. If a severe acute nephritis has developed itself in a septic case, all the symptoms may be erroneously referred to uræmia. But persistent observation will usually lead us to the right conclusion. As to the conditions of great prostration resembling acute sepsis, which occur in acute (primary) ulcerative endocarditis and in severe articular rheumatism, see the appropriate chapters.

The **treatment** can be merely symptomatic. Of course we try again and again to cut short the attacks of fever by large doses of quinine or antipyrine, but never with any but temporary success. Baths, stimulants, and, if necessary, narcotics are the other chief remedies employed.

## CHAPTER XX.

### HYDROPHOBIA.

(*Rabies canina.*)

**Ætiology. Rabies in Dogs.**—A peculiar infectious disease sometimes occurs in dogs, and more rarely in some other animals—viz., the wolf, fox, cat, cow, and horse. Men who are bitten by the animal may catch the disease, and thus become the victims of terrible symptoms originating in the central nervous system.

Two forms of madness are distinguished in dogs—the raving madness and the quiet madness. Bollinger describes the raving form as beginning with prodromata, the melancholy stage, lasting one to three days. The animal is low-spirited, timorous, and without appetite. Then comes the stage of irritation or of mania, in which the animal is attacked with an impulse to bite. It seems determined to run away and rove about, and it utters a peculiar howl. The dog will not touch his ordinary food, but often swallows straw, hair, earth, bits of wood, etc. In the third or paralytic stage paralysis appears. The dog looks lean and wretched, and always dies on the tenth day at the latest. In what is called the quiet madness there is no maniacal stage. The symptoms of paralysis, affecting chiefly the hind limbs and the lower jaw, occur earlier and are sooner fatal. Marked pathological changes are not found. There are pulmonary and intestinal catarrh and passive congestion of the viscera, and the stomach often contains foreign bodies in place of the usual partially digested food.

[On the Western plains hydrophobia is said not infrequently to follow skunk bites. The bite is inflicted during sleep on persons passing the night in the open air or in tents to which the animal can gain access.]

Rabies is transferred to the human being almost invariably by the bite of some raving animal, and this animal is almost always a dog. The poison, which is not yet known in its pure form, is evidently contained in the saliva or slaver and in the blood of mad animals, and can, by means of these substances, be successfully inoculated upon other animals. Pasteur has discovered another way to produce the disease experimentally. He takes minute portions of the brain, medulla oblongata, or some other internal viscus of a mad dog, and either injects them into the veins of a healthy animal, or trephines, and then inserts them beneath the meninges. The virulence of the rabic poison when thus manipulated undergoes, under special conditions, very peculiar alterations, which will be detailed at the close of this chapter.

The liability to rabies does not seem to be universal among human beings. About one half of those who are bitten by mad animals exhibit no subsequent symptoms. Still this can be only in part due to inherent immunity from the disease, and must in part result from imperfect infection. The duration of incubation till rabies finally breaks out seems to vary greatly. As a rule it is about three to six months, but observers have reported instances both of shorter and of much longer duration.

**Clinical History.**—The disease begins with a general feeling of indisposition, anorexia, headache, and uneasiness. This last is partially explained, to be sure, by a dread of what is impending. If the bite was in the face, frequent convulsive sneezing may occur. Even now, in this prodromal stage, a marked aversion to liquids is a usual and early symptom. The attempt to swallow excites slight convulsive disturbances. Painful sensations may arise once more in the bitten place, although this has usually been cicatrized long before, and the neighboring lymph-glands are often found to be swollen.

Only a day or two later the second, hydrophobic stage begins. The especial characteristic of this consists in the peculiar attacks of tonic convulsions. The pharynx suffers most, but convulsions also seize the muscles of respiration and those of the trunk and extremities. A terrible feeling of anxiety and oppression accompanies these attacks, so that one who has once witnessed the sight can never forget it. The convulsions always seem to be reflex, and are produced by the slightest causes, particularly by any attempt to swallow, or sometimes by the very sight of water. They recur at gradually diminishing intervals, and last from a few minutes to half an hour. The excitement of the patient may reach the pitch of delirium or mania. The pulse is full and rapid. The temperature is usually only slightly elevated, but it may be high. There is great thirst, accompanied by burning pain in the throat. Often there is marked salivation.

This condition lasts one to three days. Then death occurs, ushered in by violent convulsions. Or death may be preceded by a brief third stage of paralysis, during which there are no convulsive attacks. Cases of recovery in man, if they ever happen, are extremely rare.

The result of the autopsy is practically negative. The disease is an infectious one, and therefore we should hardly think it *a priori* certain that such objective cerebral lesions would be found as might of themselves account for the grave clinical symptoms. The microscope has repeatedly detected very minute hemorrhages, clusters of lymph-cells around the blood-vessels, etc. The throat may present the signs of catarrh. The lungs are congested, and often oedematous. The blood is dark, with few clots. The heart, liver, and spleen are apparently normal.

The **diagnosis** is usually easy, particularly if we know of the possibility of infection. We are guided by the convulsions following attempts to swallow, as well as by the whole group of symptoms. Hydrophobia is distinguished from traumatic tetanus by the absence of trismus and of the characteristic tension of the muscles of the back and abdomen, by the convulsions coming in separate attacks, and by the usually greater length of incubation. There is only one form of tetanus which bears very great resemblance to rabies, viz., the so-called hydrophobic tetanus (*vide infra*). It should be mentioned that the mere dread of hydrophobia may cause an easily excited person to have the nervous symptoms of the disease, but of course without disastrous results. Hysteria, also, may give rise to convulsions on swallowing somewhat resembling those of hydrophobia.

However hopeless **treatment** seems, we must at least try to mitigate the patient's suffering. Narcotics accomplish this best—e. g., opium or chloral, or, most

useful of all, the inhalation of chloroform. Curare has been administered repeatedly, and does seem to lessen the violence of the attacks.

Prophylaxis is extremely important. We can not consider in detail the regulations (muzzling) which the government should make in order to prevent the spread of the disease. As to individual prophylaxis, every suspicious bite should be very thoroughly disinfected, and then cauterized either with nitrate of silver, caustic potash, or the red-hot iron. It has also been recommended that the entire wound or scar should be excised, along with any swollen lymphatic glands which may be found in the neighborhood. Internal remedies to prevent the outbreak of the disease are probably quite useless. Cantharides, belladonna, calomel, and arsenic have been given for this purpose, but without success. On the other hand, Pasteur has recently made a series of extremely remarkable observations which have led to a special method of prophylactic inoculation against rabies in human beings. If a bit of the spinal marrow taken from a mad dog is introduced beneath the dura mater of a rabbit by means of trephining, the animal exhibits the symptoms of rabies after fourteen days' incubation. If in the same way a second rabbit is inoculated from the first, and so on, the virulence of the inoculated material increases gradually with every inoculation, while the period of incubation grows shorter and shorter, till it lasts but seven days. Beyond this point the period of incubation does not seem to diminish. If, on the other hand, the same series of inoculations are made on apes, the virulence of the poisonous matter does not increase, but diminishes. And if dogs are inoculated with material artificially attenuated in this manner, the animals remain in good health, and furthermore attain an immunity against more virulent inoculations, so that they may be bitten by mad dogs without becoming infected.

Pasteur has also announced a still more simple and valuable method of artificial attenuation of the virus. He removes small portions of the spinal marrow of rabbits which are suffering from rabies in its most violent form produced by the above detailed method, and these bits of marrow he exposes to air which has been wholly deprived of moisture. In this way the poison contained in the spinal marrow gradually and progressively loses its virulence, until it finally becomes inert. A portion of spinal marrow which by long drying has completely lost its original virulence is then rubbed up in sterilized bouillon and injected into some animal—for instance, a dog—and then in regular succession pieces of marrow which have been dried for shorter and shorter periods and so contain more and more of the poison, until finally the point is reached when it is possible to use for the injection pieces which are perfectly fresh and extremely poisonous, without affecting the animal's health. That is, the animal has attained immunity from the disease. This second method has now been employed by Pasteur on several thousands of human beings who were said to have been bitten by mad dogs; and he claims that only a comparatively small number of the individuals inoculated by him have eventually suffered from rabies.

It is true that many doubts are still expressed with regard to the practical value of Pasteur's investigations. The above detailed experimental observations must, however, have some foundation in fact, although they should be tested carefully and repeatedly. If we compare Pasteur's statements with the facts known about prophylactic inoculation with anthrax (see the appropriate chapter) and about vaccination, we certainly can not restrain the thought that we are here upon the threshold of discoveries the future significance of which is immeasurable.

---

## CHAPTER XXI.

## GLANDERS.

(Farcy.)

**Etiology.**—Glanders is a disease of the horse and some animals allied to it—viz., the ass and mule. It can, however, be transferred to man. It is characterized by peculiar new growths, either like nodes ("farcy-buds"), or more rarely diffuse. These are very prone to suppurate and break down. Such nodes, and the ulcers which they leave behind them, occur most frequently in the mucous membrane of the nose. In horses the purulent nasal discharge is one of the earliest and most important symptoms of the disease. Similar nodes are found in the larynx, lungs, liver, spleen, and kidneys, and often also in the skin. The cutaneous swellings and deep, crater-like ulcers belong to that form of the disease which is called "farcy." The corresponding lymphatic vessels and glands are usually much swollen. The animal has fever, grows weaker and weaker, and almost invariably dies at the end of one to three weeks.

Glanders in man is always referable to infection from a diseased animal, although in certain instances it is impossible to demonstrate the source. The disease is therefore commonest among persons who have much to do with horses—e. g., hostlers, coachmen, farmers, and cavalrymen. The virus is usually conveyed by the pus and nasal secretions of the diseased animals. A little of this falls upon some excoriation on the hand or some crack in the skin, and is absorbed. Man does not seem very liable to the disease; it is of rare occurrence.

Löffler and Schutz have discovered the specific disease-producing agent. These investigators were able to demonstrate in all the products of glanders delicate bacilli about the size of the bacilli of tuberculosis. These bacilli could be reared artificially, and, if inoculated upon horses and other animals, gave rise to a typical attack of glanders in every instance. The bacilli of glanders can scarcely ever be detected in the blood. It is also very interesting that they rapidly lose their virulence in purified cultures outside of the living body. This is one more proof of the fact, which is lately coming more and more into prominence, that the external influences surrounding the life of bacteria modify greatly their biological peculiarities.

**Clinical History.**—The period of incubation lasts about three to five days, and sometimes longer. The first symptoms are local, if the infection has resulted from a visible injury. There is considerable swelling and pain in this spot, and usually considerable lymphangitis in its neighborhood. In other cases, however, the disease begins with indefinite constitutional symptoms, such as fever, headache, and pain in the limbs, so that there may be some resemblance to a beginning typhoid fever. The local and general disturbances increase, and the disease soon attacks other parts of the body. There are usually pustules, or larger abscesses in the skin. These burst and discharge offensive pus, leaving behind them irregular, deep ulcers. Not infrequently the joints are swollen. The mucous membranes are also attacked; chief among these troubles are ulcers in the nose. The nose swells as if with erysipelas, and there is a purulent, foul-smelling discharge. The nose rarely escapes. The conjunctivæ, throat, mucous membrane of the mouth, and the larynx also undergo inflammation and ulceration. A violent, diffuse bronchitis develops. Sometimes there is considerable disturbance of the stomach and intestine, giving rise to vomiting and diarrhœa. At the same time the constitutional symptoms become more and more severe. The patient grows stupid or delirious. In some few cases the severe cerebral symptoms are due to a purulent meningitis, perhaps through extension of the inflammation by contiguity from

the nose. The fever is high. Sometimes it is quite continuous. More rarely there are chills and great elevations, as in the fever of pyæmia. The pulse is rapid and small. The spleen is seldom much enlarged. The urine may contain a trace of albumen.

In these severe acute cases the termination is almost always fatal. Death occurs at the end of about two to four weeks. There are cases with a more chronic course, with tedious persistence of the troubles in the skin and mucous membranes, and milder febrile and constitutional symptoms. Such attacks appear at first tolerably favorable, but may later assume the acute form, or they may run on for months, and at last end in complete recovery.

The **autopsy** reveals a condition greatly resembling that in pyæmia. We find abscesses in many parts, particularly the muscles and the lungs, and, next in frequency to them, the spleen, brain, and other viscera. In the mucous membrane of the nasal cavities, the pharynx, and the larynx, are found nodes and ulcers, such as occur in the horse. As in septicæmia, there are often numerous hæmorrhages into the serous and mucous membranes. It has already been mentioned that the specific bacilli of glanders are present in the abnormal secretions.

**Diagnosis.**—Without the aid of ætiological factors the diagnosis of glanders is often very difficult. Indeed, until recently there have been instances where even the autopsy did not suffice to exclude pyæmia. But now that the specific bacilli have been discovered we can clear up all doubts. We can not, however, enter into a particular description of the distinguishing characteristics of these bacilli. Their demonstration requires pure cultures. At the bedside also ætiology is all-important in diagnosis—e. g., exposure to infection, or occupation. Experience with a limited number of cases renders it probable that in the future we shall be able to demonstrate the bacilli, during the life of the patient, in the nasal secretions or the contents of the abscesses. The most characteristic symptoms are the nasal and cutaneous. In a case that takes a chronic course there is a possibility of mistaking the cutaneous ulcers for syphilitic sores.

We have already implied that the **treatment** of acute cases is almost hopeless. We must do all we can in the way of cleanliness and disinfection to improve the local condition of the skin, the nose, and the throat. Appropriate agents are carbolic and salicylic acids and chlorine-water. Further treatment, by means of baths, quinine, and stimulants, should be in accordance with the general rules for the care of severe acute infectious diseases. Potassic iodide has been recommended as an internal remedy.

## CHAPTER XXII.

### MALIGNANT PUSTULE.

(*Anthrax. Charbon. Splenic Fever. Mycosis intestinalis. Carbunculus contagiosus.*)

**Ætiology.**—The cause of malignant pustule is the infection of the body with a specific kind of bacilli, the *bacillus anthracis*. This organism was discovered by Pollender in 1849, and a few years later, independently, by Brauell.

These bacilli are very minute cylinders, about seven to twelve micromillimetres in diameter. They are found in enormous numbers in the blood and organs of animals which die of anthrax. Aniline-staining makes them more easily visible. By means of blood containing the bacilli, Davaine (1863) and others have inoculated many animals with the disease, including mice, rats, guinea-pigs, cows, sheep, goats, and birds. The bacilli can also be isolated and

cultivated, and then produce infection. This is proof positive that they are the actual carriers of contagion. The rapid increase of the anthrax bacilli in the blood goes on by subdivision. In the artificial cultivations, however, the bacilli grow, as Koch has shown, into quite long threads, in which shortly appear minute, brilliant egg-shaped bodies (cf. Figs. 12 A and 12 B). The threads become disintegrated, setting free the little shining ovoids, the spores of anthrax, to grow into

FIG. 12A.—Anthrax bacilli. (From KOCH.) 650 diameters. A, from the blood of a guinea-pig. B, from the spleen of a mouse after three hours' culture in the aqueous humor.

by spores as by full-grown bacilli. There are facts which render it not improbable that the anthrax bacilli exist in other places than the bodies of men or ani-

FIG. 12B.—Anthrax bacilli; spore formation and spore germination. (From KOCH.) A, from the spleen of a mouse after twenty-four hours' culture in the aqueous humor, spores arranged like strings of beads in the filaments. 650 diameters. B, germination of the spores. 650 diameters. C, the same, with a higher power. 1650 diameters.

mals, and may there complete their circle of development. Such places are marshes, the banks of streams, and the like. If it is possible for them to be carried by high water to the pasture lands, we have an explanation of those sudden endemic appearances of anthrax which sometimes occur in places previously free from the disease.

Anthrax in animals is of great practical importance, because its favorite victims are the herbivorous domestic animals—viz., the cow, sheep, and horse. Among these it is terribly destructive. It is remarkable that the carnivora enjoy almost complete immunity. The disease usually runs a very acute course in animals. Indeed, it often seems like apoplexy; the apparently healthy animal suddenly falls, suffers for a few minutes from convulsions and dyspnoea, and dies. Other cases have a somewhat longer and more intermittent course, but in these also recovery is very rare.

Probably human beings are infected in most cases by direct inoculation. Shepherds, farmers, butchers, and others who come in contact with animals suffering from anthrax, are liable to infection through any little wound or scratch upon the hands. Very often the disease is caught from hides, hair, or other parts of dead animals. In workshops and factories where wool and hides have been used which came from diseased animals, anthrax has repeatedly occurred. Carriers, rope-makers, paper-makers, and those who handle horse-hair and wool, are all exposed. Anthrax has also earned the name of "rag-pickers' disease." Another way of infection, supposed to happen among animals as well as men, is through the sting of insects—e. g., flies—bringing the poison from diseased animals. It is not likely that the virus can be absorbed through the unbroken skin, or by the lungs. It is certain, however, that the intestine may afford ingress to the infectious matter. Koch has proved this by putting spores in the food of sheep. Intestinal mycosis in man (*vide infra*) may very possibly be due to a similar mode of infection. Many cases of poisoning from eating meat have been referred to the ingestion of the flesh of animals who died from anthrax.

**Clinical History.**—Anthrax in man has two distinct forms. These may appear in combination. The first begins with a local disorder of the skin at the point of infection—viz., the malignant pustule, or anthrax carbuncle. The second and rarer form presents the symptoms of a severe acute constitutional infection. An accompanying cutaneous disorder is sometimes observed.

1. The **malignant pustule** usually comes on the hand, the arm, or the throat, and appears from three to seven days after infection. A vesicle forms at the infected spot, grows rapidly, becomes excoriated, and usually takes on a characteristic appearance, being of a dark-bluish or black color. The surrounding parts become diffusely swollen and red. Secondary vesicles may surround the original one. The swelling becomes more and more extensive. Inflamed lymph-vessels or veins radiate in red lines from the pustule, and the neighboring glands are also affected. These appearances are accompanied by fever, and more or less prostration. In a favorable case the swelling subsides, the scab falls off, and there is at last complete recovery. But in other cases the constitutional infection becomes more and more prominent, and eclipses the local disorder. The fever and prostration increase. Severe intestinal symptoms appear, or else stupor, delirium, and other nervous disturbances; and death may ensue after a few days' illness.

2. **Intestinal Mycosis.**—A better name would be intestinal anthrax. A quite different picture is presented by this second form, which gets its name from the marked intestinal lesions. In this the cutaneous disorder, if it exists at all, is insignificant, compared with the severe constitutional disturbance. It is only within a few years that the labors of Buhl, Waldeyer, E. Wagner, Leube, and others have shown that attacks of this kind have any connection with anthrax. So few cases have thus far been observed that it is impossible at present to give a definite and complete description of the disease.

In cases of this sort the attack is usually rather sudden, beginning with chilliness, vomiting, headache, and languor. The diagnosis is usually very obscure at first, unless the calling of the patient suggests the possibility of anthrax. On careful examination, we may find some places where the skin is broken, or possibly a small characteristic pustule. In a case which came under our own observation a pustule had existed on the back of the right hand for some weeks before severe symptoms appeared, but had not attracted the attention of the patient at all. In this case, therefore, the constitutional infection seems to have come from the local disease. But in other cases cutaneous troubles, in the form of small carbuncles may occur secondarily in the course of the disease. Hemorrhages into the skin and mucous membranes also occur.

Of other symptoms, the gastro-intestinal deserve to be mentioned first. Vomiting occurs frequently, and also a moderate, painless, and sometimes bloody diarrhoea. There is usually severe dyspnoea, and a marked sense of oppression in the thorax, but without objective pulmonary signs. Very soon there is collapse; the nose and extremities grow cool; the pulse is rapid, but small; and there is lividity. In a few instances tetanic or epileptiform convulsions have been observed. The temperature is seldom much elevated. It may be subnormal. In a few days the prostration becomes complete, and death ensues.

Milder forms apparently occur, but here the diagnosis may not be absolutely certain. We have seen a few such cases originating in a rope-walk where Russian hair was used. The constitutional symptoms were only moderately severe, the fever was mild, and recovery occurred after about two or three weeks.

**Pathology.**—In the fatal cases of anthrax the intestinal lesions are the most characteristic. Besides the signs of catarrhal inflammation, we find peculiar lesions in the mucous membrane of the small intestine, and sometimes in the upper portion of the colon. These consist of dark, infiltrated spots, with hæmorrhages, the spots being somewhat larger than a silver dime. The microscope reveals numerous collections of anthrax bacilli, situated chiefly in the lumen of the blood-vessels. The spleen is usually only moderately enlarged, but dark and congested. There may be ecchymoses in the kidneys, the brain, and the serous membranes. Often there is swelling of the lymph-glands. In one case which we saw, with slight intestinal lesions, the mesenteric glands were considerably enlarged, and the bronchial lymph-glands were perfectly enormous. The bacilli are found in all the organs mentioned.

The **diagnosis** of a malignant pustule is seldom difficult, particularly if attention be directed to the aetiology. All doubt is over if we find the bacilli. The cases of intestinal mycosis may be more obscure. Here, too, the demonstration of bacilli in the blood is, of course, of the greatest importance, but reports have thus far been scanty of endeavors to find them during life in man.

**Treatment.**—1. Prophylactic inoculation. Toussaint and Pasteur were the first to show that the virulence of anthrax bacteria can be artificially diminished by certain external influences. If the bacilli are kept under cultivation for several weeks at an unchanging temperature of 106° to 107·5° (42°–43° C.), they preserve their external appearance completely, as well as their ability to grow, but gradually lose their power of infection. Inoculations made with this "vaccine virus" produce at most an insignificant disturbance. But what is especially remarkable is that the animals thus vaccinated are said to enjoy immunity thereafter from infection with actual anthrax. Pasteur was the first to make this assertion; and he proposed that the prophylactic inoculation of sheep and other animals liable to anthrax should be undertaken on a large scale, promising the farmers that very great benefit would result. This promise has not yet been completely fulfilled, although there can be no doubt that in general Pasteur was correct. Experiments instituted by Koch and others have shown that, although Pasteur's vaccination protects against the artificial inoculation of anthrax, it does not, at least as now performed, afford immunity from the natural anthrax, which usually results from infection within the intestine. French investigators have lately made known new methods of producing an artificial diminution of the growth and virulence of anthrax bacilli, and in part also of other varieties of bacteria. Chauveau has found that cultures of anthrax bacilli exposed for several days to an atmospheric pressure of three to twelve atmospheres, or to compressed oxygen, lose a portion of their virulence; and that animals inoculated with bacilli thus attenuated gain an immunity to inoculations with the original anthrax poison. The statements of Arloing are very remarkable. He says that the direct play of sun-

light, or even of a concentrated artificial light, upon the cultures exercises a restraining influence upon the growth and poisonous properties of the bacilli, and that inoculation material weakened in this way may be employed for the protection of animals.

2. The treatment of malignant pustule is surgical. Cauterization is often tried with such materials as caustic potash, nitric acid, or carbolic acid; but it should always be borne in mind that such manipulations may easily contribute to a local extension of the anthrax poison. For the same reason one should hesitate to incise or to excise the pustules. We are therefore usually obliged to confine ourselves to the prescription of a suitable position for the affected member, and the application of an ice-bag over the diseased spot. The treatment of intestinal mycosis must be purely symptomatic. We may try the effect of calomel, salicylic acid, stimulants, and baths.

## CHAPTER XXIII.

### TRICHINOSIS.

(*Trichinatus disease.*)

**The Natural History of Trichinæ.**—The *trichina spiralis*, one of the class of round worms or nematoda, has long been known to occur occasionally in the muscles of men and certain animals; but it was not until 1860 that Zenker showed that trichinæ are capable of exciting in man a dangerous and sometimes fatal disease. Since then numerous individual cases and quite extensive epidemics have been reported; and the labors of Virchow, Leuckart, and others have taught us the anatomy and mode of development of this peculiar parasite.

The trichina appears in two shapes—as intestinal trichina and as muscular trichina. The intestinal form is a small white worm, visible to the naked eye. The female is 3-4 mm. long, the male only 1-1.5 mm. They have well-developed digestive and sexual organs. The male is distinguished by two little processes at the tail. The muscular trichina (*vide* Fig. 13) is a small worm 0.7-1 mm. long. It is found coiled up among the muscular fibers, inside a connective-tissue capsule, which is often calcified.

The events in the life of the trichina are remarkable. If living muscular trichinæ reach the human stomach, viz., through the eating of trichinatus pork, the capsules are dissolved, and the trichinæ, thus set free, grow in two or three days into sexually perfect intestinal trichinæ. In the uterus of the impregnated female the eggs develop into embryos, which are born already hatched. The birth of embryos begins seven days after the ingestion of the muscular trichinæ, and seems to continue for some time. A single female is said to produce more than one thousand embryos. These latter begin their travels soon after birth, and reach the voluntary muscles. As to the routes they choose we are still somewhat in doubt. Some authorities state that the trichinæ penetrate through the walls of the intestine and the abdominal cavity into the connective tissue. Others affirm that they enter the lymphatic vessels, or exceptionally the blood-vessels. They penetrate into the primitive fibers of the muscles, and cause them to disintegrate. Finally, they coil themselves up, attain the size of muscular trichinæ in about fourteen days, and become encapsulated. Each capsule usually contains but one, although it may inclose as many as four. The capsule is formed partly by an excretion from the trichina, and partly from the reflex hyperplasia of the surrounding connective tissue. The process of development is now complete. The muscular trichinæ seem, unlike the intestinal form, to have a very long lease of life, and usually

endure till the death of their host. They are often found accidentally at autopsies. They are most abundant in the diaphragm, the intercostal muscles, the muscles of the larynx and throat, and in the biceps.

**Ætiology of Trichinosis.**—The only cause yet known for trichinotous disease in man is the ingestion of trichinotous raw or underdone pork—e. g., smoked ham.

Swine are pre-eminently subject to trichinae. They probably become infected in various ways, e. g., from the fæces of human beings and swine suffering from trichinosis, or through the ingestion of the trichinotous flesh of other swine. The waste of slaughter-houses is often fed out to swine, and the disease thus disseminated. Many affirm that swine are also infected by eating rats infested with trichinae.

**Clinical History.**—The symptoms in man correspond in general to the developmental and vital processes of the trichinae, as above depicted. In individual cases, however, the separate stages are quite often obscured, probably because all the parasites do not develop simultaneously, or because there are relapses. The first symptoms are gastro-intestinal. At the commencement there is a feeling of pressure in the epigastrium, with nausea and vomiting. Later, diarrhœa is prominent, becoming in some cases so violent as to remind one of cholera. It is not impossible, although rare, to find intestinal trichinae in the stools. Sometimes there is constipation instead of diarrhœa. In some cases the initial gastro-intestinal symptoms are but slight. Frequently, even in the beginning of the disease, there is complaint of pain and stiffness in the muscles, too early for it to be due to the migrations of the trichinae.

The genuine severe muscular symptoms, due to the myositis produced by the trichinae in the muscles, do not begin till the second week, or even later. In many cases, where the invading parasites seem to be relatively few in number, the muscular symptoms are slight, or wholly absent. In the more severe cases, however, they may be extremely violent and distressing. The muscles become swollen, firm and hard, very tender on pressure, and very painful. The patient avoids all movements and contraction of the muscles as much as possible, lying,

FIG. 13.—(From HELLER.) An isolated primitive bundle with two free trichinae in the sheath of the sarcolemma. Much enlarged.

with flexed arms and with legs either extended or likewise flexed, motionless in bed. The patellar reflex almost always disappears, and on testing the electrical reactions there is found a considerable diminution of muscular excitability to both the galvanic and faradic currents, sometimes associated with delayed contractions, and abnormally long duration of the same after the stimulus ceases (Eisenlohr). The masseters and the pharyngeal and laryngeal muscles are attacked, so that there is difficulty in mastication and deglutition, and hoarseness. The participation of the *motores oculi* causes pain in the eyes. The condition of the diaphragm, intercostals, and abdominal muscles causes serious difficulty in respiration. There is distressing dyspnœa, and expectoration is so hampered that secretions accumulate in the air-passages. Some of the fatal cases of trichinosis are principally due to this impairment of respiration. The condition may be aggravated by diffuse bronchitis or lobular pneumonia.

Third in the list of important symptoms comes oedema. It appears, toward the end of the first week, in the eyelids. Somewhat later it involves the upper and lower extremities. What produces it is not quite clear. It has been regarded as in part inflammatory and in part the result of occlusion and thrombosis of the smaller lymphatics. Cutaneous eruptions also develop—e. g., vesicles, wheals, petechiæ, and pustules. Frequently there is profuse perspiration, consequent upon which abundant crops of miliaria or sudamina may appear.

In well-marked cases there may be quite high fever and other severe constitutional symptoms in addition to the local disturbances already discussed. The temperature may for a time reach 104° to 106° (40°–41° C.); but the fever is seldom continuous for any length of time, being usually interrupted by frequent and considerable intermissions. There are also a rapid pulse, headache, stupor, and other symptoms suggesting typhus or typhoid fever. In fact, the first case in which trichinosis was recognized at the autopsy (by Zenker of Dresden) had been regarded before death as typhoid. The urine may be albuminous; and, in rare instances, nephritis is seen.

The duration of the disease varies widely. There are mild cases often unrecognized, which get well after slight symptoms have lasted two or three weeks. More pronounced cases occupy six to eight weeks, or even a much longer time. Of the more severe cases about one third prove fatal, usually from the fourth to the sixth week. Sometimes death is caused by the severity of the constitutional disturbance, but usually from disabled respiration. Even if the case ends favorably, recovery is often very tedious.

**Pathology.**—The autopsy reveals little that is characteristic excepting the changes in the muscles. There are sometimes the signs of hæmorrhagic catarrhal inflammation of the small intestine. The spleen is not enlarged. Very often the liver is decidedly fatty. What should cause this in trichinosis has not yet been determined. The lungs often present islets of lobular pneumonia, or even sometimes of gangrene. The trichinæ are found in the muscles, beginning with the fifth week. They can be recognized by the naked eye as little whitish lines. We have already named the muscles chiefly infested. Under the microscope we see the fibers in which the trichinæ lie transformed into a fine granular mass. The nuclei of the muscular fibrillæ are greatly increased in number in the neighborhood of the coiled-up parasite. Finally, the sarcolemma collapses, and becomes greatly thickened upon its external surface by a hyperplasia of connective tissue. The muscles also present many other degenerative changes, such as a flaky disintegration, waxy degeneration, and the formation of vacuoles. There is furthermore a marked increase of nuclei in the interstitial tissue of the muscles. Within the intestines are sometimes to be found, even after several weeks' illness, numerous living intestinal trichinæ—a fact of importance from a therapeutic point of view.

**Treatment.**—The trichinæ may still be alive in pork that has been smoked or salted or half-cooked—e. g., many sausages are unsafe. The only possible prophylaxis, as far as the individual is concerned, is therefore to avoid all such food. A real protection for the public against the disease is also afforded by governmental microscopic inspection of meat, as already established in many places.

When an individual has become infected with trichinæ, if it is possible that intestinal trichinæ still are present, the treatment must always begin with the exhibition of purgatives, such as compound infusion of senna, calomel, or castor-oil. Of the remedies which are calculated to destroy the intestinal trichinæ, glycerine, which was first recommended by Fiedler, seems to be the most efficient. It must be given in rather large doses, say a tablespoonful every hour. Other

drugs are much less reliable, but we will name among them benzine in the dose of one to two drachms (grm. 4 to 8) in capsules, and picric acid in pills—the daily dose being 5 to 8 grains (grm. 0·3–0·5).

Later on, when the invasion of the muscles has already begun, we are unfortunately almost without resource. The muscular pains can be alleviated by narcotics, particularly morphine subcutaneously, poultices, and chloroform-oil as an embrocation.\* Protracted warm baths are excellent. Antipyrine and salicylic acid are also said to do good in many cases.

---

\* Generally one part of chloroform to ten of olive-oil. It is not officinal in Germany, but is weaker than the linimentum chloroformi (U. S. P.).—TRANS.

# DISEASES OF THE RESPIRATORY ORGANS.

## SECTION I.

### DISEASES OF THE NOSE.\*

#### CHAPTER I.

#### CORYZA.

(*Snuffles. Rhinitis.*)

**Ætiology.**—The well-known symptoms of coryza depend upon a catarrhal inflammation of the nasal mucous membrane. Although this catarrh may often be due to infectious influences, still we can not deny that it is one of those diseases which may be caused by taking cold. Daily experience teaches us how often coryza follows an evident exposure to cold, like wetting the feet. We may mention its contagiousness as an argument in favor of its infectious character, and this may be illustrated by the fact that it may be conveyed by handkerchiefs, kissing, etc., but an experimental transmission of common coryza has not yet been successful.

Coryza may also arise from the action of chemical irritants or mechanical irritants, like dust, on the nasal mucous membrane. The iodine coryza, which occurs from the internal use of iodine, is especially noteworthy. In this form iodine can easily be detected in the nasal secretion. The idiosyncrasy of many people to ipecacuanha is also well known, the very smell of it setting up a coryza. A severe coryza is the chief symptom, too, in hay fever,† which is probably due to the action of the pollen of certain grasses on the respiratory mucous membrane.

---

\* Special treatises on the pathology and therapeutics of nasal diseases are to be found in the following works: Michel, "Krankheiten der Nasenhöhle." Fraenkel, "Diseases of the Nose," in "Ziemschen's Cyclopaedia." Störk, "Klinik der Krankheiten des Kehlkopfes, der Nase, und des Rachens." Scheeh, "Krankheiten der Mundhöhle, des Rachens, und der Nase." Moldenhauer, "Krankheiten der Nasenhöhlen," etc.

† The disease called hay fever (*catarrhus æstivus*) is of frequent occurrence in England and North America, although rare with us in Germany. It usually affects men in middle life, less often women. Some individuals are peculiarly liable to the disease. For them an attack may be produced merely by walking across a meadow or near a grain-field at that season when the grasses are in bloom, i.e., about May to July. As already intimated, it is supposed that the grains of pollen excite the disease, being diffused in the air and thus drawn into the nostrils. At any rate, they have repeatedly been found in the nasal secretion and also in the tears of affected persons. The symptoms consist in a very severe coryza, with burning of the nose and violent sneezing. The erectile tissue of the nose is probably acutely swollen. Usually these symptoms are accompanied by a well-marked conjunctivitis with oedema of the eyelids. In severer cases there is furthermore a catarrh of the larynx and bronchi. There is frequently a tendency to violent attacks of asthma ("hay-asthma"), especially at night (see the chapter on bronchial asthma). The treatment consists first in avoiding the cause by change of residence, as by going to the sea-shore. For the nasal catarrh douches are chiefly recommended, such as a solution of 1 part of quinine to 500–1,000 parts of water, or a solution of carbolic acid. The administration of iodide of potassium might be tried, particularly where there is asthma.

Finally, we must bear in mind that coryza may often be only a symptom of another disease like measles, syphilis, or glanders, and that severe purulent inflammation of the nasal mucous membrane may be excited by the presence of the secretion from a gonorrhœal or blennorrhœal conjunctivitis.

The **symptoms** of coryza are in most of the milder cases of a local nature only. The secretion is troublesome; at first it is scanty and mucous, but later it becomes more abundant and watery; and sometimes it is purulent. The nasal passages are not infrequently closed from the swelling of the mucous membrane. The patient necessarily has to breathe through the mouth, which explains the well-known nasal speech. This closure of the nares may give rise to dangerous attacks of dyspnoea in children, especially in infants, who have to breathe through the nose when sucking at the breast. The sense of smell is always diminished. The local sensations of pain and burning are due chiefly to a mild inflammation of the skin of the nostrils and upper lip set up by the irritation of the secretion. The irritated condition of the inflamed mucous membrane occasions a feeling of tickling and itching in the nose, and frequently by a reflex action violent sneezing. The symptoms are more severe if the cavities adjacent to the nose are attacked by catarrh, and if in them accumulations of secretion occur. Marked pain in the forehead occurs in catarrh of the frontal sinuses. The sinuses of the ethmoid and sphenoid bones, and the antrum of Highmore, may also be implicated. Much more frequently a severe coryza sets up an inflammation in adjacent mucous membranes. Thus we find following a coryza a conjunctivitis, an affection of the ear, a sore throat, or a laryngitis. In persistent coryza an eczema is not infrequently excited on the skin of the upper lip, and mention has already been made of the fact that coryza may sometimes act as the exciting cause of an erysipelas.

In severe coryza we may sometimes have quite a marked general disturbance, and often slight elevations of temperature. The "coryza fever" in children, for instance, is well known.

**Treatment.**—Special treatment is usually unnecessary, for most cases recover of themselves in a few days. With abundant secretion, especially in fresh cases, Hager's "coryza remedy" [as an inhalation] is worthy of trial; this consists of ten parts each of alcohol and carbolic acid, and five parts of ammonia-water. A snuff of calomel is also greatly praised. When the secretion forms abundant dry scabs, an attempt should be made to wash them out by injections of warm fluids, like warm milk. The upper lip and the nostrils should be smeared with vaseline or simple ointment to protect the skin from the action of the secretion. Only in the rare cases of a severe purulent catarrh can an energetic local treatment of the nasal mucous membrane be necessary. Here we may use douches, sprays, or inhalations of astringents like tannin or alum, or we may apply caustics like nitrate of silver.

---

## CHAPTER II.

### CHRONIC RHINITIS.

(*Rhinitis chronica hypertrophica and atrophica. Ozena.*)

**1. Chronic Rhinitis.**—It is in many cases impossible to determine the causes of hypertrophic rhinitis. Sometimes the condition seems to develop as a sequel to frequently repeated nasal catarrh, although in this case the relation is often reversed—it being the chronic rhinitis which occasions a predisposition to the frequent acute exacerbations of the catarrh. Certain diatheses (anæmia, scrofula)

appear to influence the development of the disease. This is also true of occupations which expose the individual to dust or smoke, and sometimes of malformation of the nose (for instance, deviation of the septum) and perhaps also of hereditary predisposition.

The anatomical changes consist in a slow but progressive swelling and hypertrophy of the mucous membrane. This seems spongy, and of a red or reddish-gray color. The greatest change is almost always found over the inferior turbinated bone, and next to that over the middle. In advanced cases the mucous membrane presents rough, uneven swellings, and even polypi. These changes are often visible upon inspection of the nostrils anteriorly, but they may escape discovery until a rhinoscopic examination of the posterior choanæ is made.

The disturbance occasioned by chronic hypertrophic rhinitis may be very considerable. Nasal respiration is obstructed, the voice nasal, the senses of smell and taste impaired. The nasal secretion is for the most part increased, but it may be diminished. Often there is a tendency to nose-bleed. Many patients complain also of headache.

The frequent involvement of neighboring organs is important. This applies particularly to the ear. Deafness is caused both by the obstruction of the openings of the Eustachian tubes, and not infrequently also by extension of the catarrh to the lining membrane of the tubes and the middle ear. Very frequently the disease is associated with chronic naso-pharyngitis or pharyngitis. The visible portion of the nose is not infrequently affected, as shown by redness and swelling of its tip.

A fact of especial interest is that such a diseased state of the nasal mucous membrane may give rise to reflex neuroses (Voltolini, Hack, and others). Although, in our opinion, many of the specialists on the nose go too far in this direction, there is no room for doubt that attacks of migraine, vertigo, certain varieties of headache, and, above all, many forms of bronchial asthma, may bear a close relation to diseases of the nose. We shall revert to this point later on. (See especially the chapter on bronchial asthma.)

The *treatment* of chronic hypertrophic rhinitis, in order to be successful, demands complete destruction and removal of the hypertrophic portions by means of the galvano-cautery. For particulars, we must refer to the directions of specialists. In milder cases, however, benefit may follow the insufflation of a powder composed of one part of nitrate of silver to ten or twenty of common starch, or applications of lunar caustic may be made.

**2. Chronic Atrophic or Fetid Rhinitis. Ozæna Simplex.**—This frequent and peculiar form of chronic rhinitis is the cause of that well-known condition which is characterized by a peculiar and extremely disagreeable odor from the nose, which is therefore usually termed ozæna, from the Greek word *ὀζειν*, to stink. The disease consists in a slow, progressive atrophy not only of the mucous membrane with its vessels and glands, but finally also of the bones, and this atrophy is not preceded by hypertrophy. Thus the nasal cavities become abnormally large. The turbinated bones grow smaller and smaller, so that finally they are represented merely by narrow ridges. Furthermore, the scanty purulent secretion has a tendency to dry up and form adherent greenish-yellow scabs and crusts, which undergo a peculiar putrefactive decomposition and give rise to the unbearable stench. It is possible, but not yet demonstrated, that a specific kind of bacterium plays a part in the process.

The ozæna generally develops in childhood. It usually begins insidiously, but in other cases apparently is a sequel of some acute disease, such as measles. Anæmia and scrofula deservedly rank as important predisposing causes.

The subjective symptoms are often not marked. This is partly explained by

the fact that the patient has usually completely lost his sense of smell, but for that very reason the discomfort of his friends may be the greater. The feeling of dryness in the nose may prove annoying, and there are often complaints of headache and of pressure in the eyes. Inasmuch as the naso-pharynx and the posterior pharyngeal wall are almost always implicated in the process, the patient often suffers from hacking and a tendency to cough and vomit. Such portions of the secretion as are swallowed sometimes give rise to a considerable chronic disturbance of the stomach. Upon physical examination we are first struck by the unusual breadth of the nostrils. With the rhinoscope the extent of the atrophy is still better seen. The mucous membrane is pale or slightly red, and covered with dry scabs. Sometimes superficial ulcers are formed. Usually, as we have said, the superior portion of the pharyngeal mucous membrane shares in the disease. The posterior wall of the pharynx is seen to be atrophied, smooth as if it were varnished, and often covered with crusts. The process may involve the soft palate, and even the larynx, and not infrequently the disease is associated with inflammation of the middle ear.

It should be added that the true ozæna must not be confounded with other processes which likewise give rise to a foul smell from the nose. Tuberculous disease of the nasal mucous membrane and nasal bones is not rare, particularly in "scrofulous" children (Demme); nor should we forget the syphilitic affections of the nose, tertiary and hereditary syphilis.

**Treatment.**—The treatment of ozæna can be made effective only by the aid of local applications as prescribed by specialists. Even then the treatment is a prolonged one, and demands much patience on the part of both patient and physician. Besides local applications, we must also bear in mind the necessity of constitutional treatment, especially in syphilis and tuberculosis.

The object of local treatment is to remove the secretion in order to get rid of the bad odor. Nasal douches, with disinfectant solutions like permanganate of potassium (1-3,000) or carbolic or corrosive sublimate, are here most useful. The solution is carefully injected into the nose, or the fluid is allowed to run gently into one nostril from an irrigator while the patient keeps his head bent forward; it then runs through the naso-pharynx and out through the other nostril. The patient soon learns to retain the fluid in the pharynx and eject it from the mouth. All nasal douches must at first be used with care and under the eye of the physician. The fluid should be injected at the lowest pressure possible, so that none of it may enter the adjacent cavities or the Eustachian tube. Furthermore, all solutions used as a douche must be luke-warm—90° to 95° (25°-28° R.). Besides the regular use of douches, painting and the insufflation of powders, like boracic acid, aceto-tartrate of aluminum, etc., are sometimes employed. The insertion of tampons of dry absorbent cotton is to be recommended; under their use the secretion dries less easily and the odor is diminished. These tampons should be changed daily. It is advantageous to medicate the tampons with a one-per-cent. solution of creolin or with Peruvian balsam or some similar drug. Tincture of iodine is also recommended. Of late many attempts have been made to treat chronic nasal catarrh by the galvano-cautery. With regard to the details of this as well as of other methods, we must refer to special treatises on the subject.

---

## CHAPTER III.

## NOSE-BLEED.

*(Epistaxis.)*

ALTHOUGH in many cases nose-bleed is only a symptom of some other disease, still we are justified in a short description of it, partly because frequently repeated nose-bleeds often first call our attention to some other existing disease, and partly because the treatment is of practical importance.

Many persons are subject to habitual nose-bleed, which comes on either from slight causes, from violently blowing the nose, from physical exertion, from overheating, or even without any special cause. This habitual nose-bleed is sometimes, but by no means always, the sign of a general hæmorrhagic diathesis, which is hereditary in many families. (See the chapter on Hæmophilia.) In other cases the nose-bleed is the result of some chronic disease. It occurs especially in leukaemia, in disease of the heart, in contracted kidney, and as a symptom of the so-called hæmorrhagic diseases, like scurvy, purpura hæmorrhagica, etc. It is also not uncommon in acute febrile diseases, like typhoid and scarlet fever. Finally, diseases of the nose itself may give rise to hæmorrhage. The occurrence of nose-bleed as a form of so-called "vicarious menstruation" has often been described, but we must always be very guarded in admitting it as a fact.

In many cases nose-bleed is a very transitory symptom, wholly without danger, and in one sense it may even be advantageous. When there is headache, or a feeling of fullness in the head, there is often relief after an epistaxis. Nose-bleed is dangerous, however, when it takes place in those who are already weak and anæmic, or when it is so persistent and abundant as to cause a marked general anæmia. The latter is recognized by the pallor of the face, by the appearance of general weakness, by vertigo, tinnitus, and a weakened pulse. In such cases the physician's interference is always necessary. In every case of nose-bleed it is important to examine the posterior wall of the pharynx in order to see whether the blood is not flowing backward from the posterior nares. The hæmorrhage is often thought to stop when no more blood comes from the nostrils, and yet the blood keeps flowing posteriorly.

In every severe nose-bleed rest is the chief thing to be enjoined, and the patient must be told to avoid unnecessarily blowing, wiping, or drying the nose. By quietly and persistently closing the nostrils with a handkerchief a thrombus is often formed without any further medication, and the bleeding stops. The application of cold water (iced water), in which a little vinegar may be put, is a good thing. If the bleeding does not stop, we may next try a tampon of common absorbent cotton or styptic cotton in the nostril from which the blood comes. If this does not succeed, the posterior nares must be plugged by means of a "Bellocq's canula." In case of emergency we may use an elastic catheter, which is passed through the inferior meatus into the pharynx and out by the mouth. The tampon is fastened to the catheter and brought up into the posterior nares by drawing the catheter back through the nose. Internal remedies to check the blood are very uncertain in their action. Ergotine, in one-grain pills (grm. 0.03), every three or four hours, is the first one to employ, if we wish to try to check the bleeding by this means.

## SECTION II.

## DISEASES OF THE LARYNX.

## CHAPTER I.

## ACUTE LARYNGEAL CATARRH.

*(Acute Laryngitis.)*

**Ætiology.**—Taking cold plays a prominent part in the ætiology of acute laryngeal catarrh, as every one knows. Its influence can not properly be wholly denied, since the more intimate relation between taking cold and the origin of a catarrh is still unknown. The disposition to laryngitis differs very much in different people, so that some take a catarrh much more easily and more frequently than others. Besides cold, direct irritants which attack the laryngeal mucous membrane often set up a laryngitis; among these are in particular the inhalation of smoke and of injurious gases and vapors. Many laryngeal catarrhs, too, arise from excessive speaking, shouting, or singing, particularly if other injurious influences act on the larynx at the same time. Finally, laryngitis may appear as a complication or as a secondary affection, in other diseases, especially in measles, less frequently in typhoid, scarlet fever, and erysipelas. Catarrh of the larynx is very often combined with catarrh of the nose, the pharynx, and the larger bronchi.

**Symptomatology.**—Although the symptoms of laryngitis usually make the diagnosis easy and certain, yet an accurate understanding of the extent and intensity of the catarrh can be obtained only by a laryngoscopic examination,\* which therefore should be employed in every severe case. The laryngeal mirror shows a decided reddening and swelling of the mucous membrane, varying with the intensity of the catarrh, and most marked on the true and false vocal cords and between the arytenoid cartilages. We often see small collections of mucus here and there on the membrane. In individual cases different parts of the larynx are especially affected. In intense inflammations superficial erosions are often met with, especially on the vocal cords. In other cases the mucous membrane shows a grayish-white coloring in some places, due to a thickening of the epithelium. Small hæmorrhages in the mucous membrane are also occasionally seen. Very often we see on phonation an incomplete closure of the glottis, so that a little oval space is left between the vocal cords. This slight "catarrhal paresis of the vocal cords" is probably of muscular origin, and depends chiefly upon an affection of the thyro-arytenoid muscles.

Of the other symptoms of laryngeal catarrh, hoarseness is particularly to be mentioned, for in many cases the diagnosis of laryngitis may be made from this alone. It is either due directly to the anatomical changes of the cords, or to the paresis just mentioned. The degree of hoarseness is of course very different in different cases, and varies from a simple "roughening" or "deadening" of the voice to a complete loss of voice (aphonia).

\* More extensive observations on laryngoscopy and on many details of the pathology of laryngeal diseases, which have been carefully investigated by specialists and which can not be mentioned here, are to be found in the following works: Türk, "Klinik der Krankheiten des Kehlkopfes," 1868. Semeleder, "Laryngoskopie," 1863. Tobold, "Laryngoskopie," 1874. Störk, "Klinik der Krankheiten des Kehlkopfes, der Nase, u. des Rachens," 1880. Mackenzie, "Diseases of the Throat and Nose," 1880. B. Fraenkel and v. Ziemssen, "Diseases of the Larynx," in Ziemssen's "Cyclopaedia." Gottstein, "Krankheiten des Kehlkopfes," third edition, 1890. Schrötter, "Vorlesungen über die Krankheiten des Kehlkopfes."

The cough in laryngitis may be very severe, and is often recognizable by its harsh, hoarse ring as a "laryngeal cough." It is at first usually dry, and later on it is associated with a scanty muco-purulent expectoration, which is sometimes tinged with blood.

Pain in the larynx is generally only moderate. The subjective symptoms consist chiefly of a disagreeable feeling of itching, burning, and dryness in the throat. After prolonged speaking, however, the pain in the larynx may sometimes be quite severe. External pressure on the larynx is often somewhat painful. Difficulty in swallowing, when it occurs, is usually due to an accompanying pharyngitis, but it may also be dependent upon an affection of the epiglottis and the arytaenoid cartilages.

The general health is affected in very different degrees. Many patients feel quite well except for the hoarseness, while others are affected with considerable debility, mild headache, and even at times slight febrile disturbances.

Dyspnoea is not present in the common laryngitis of adults, even if there is decided swelling of the false vocal cords or of the ary-epiglottic folds. There is, however, a severe form of acute laryngitis, the so-called *laryngitis hypoglottica acuta gravis* (*chorditis vocalis inferior*), affecting not only children, but adults, in which well-marked symptoms of suffocation may be present. In this form there is an acute, very well marked swelling of the mucous membrane in the inferior, "sub-chordal," laryngeal space, which leads to a stenosis.

In children, however, on account of the greater narrowness of the child's larynx, symptoms of stenosis are not rare even in the milder forms of laryngitis, and therefore they have led to the establishment of a special disease, the so-called false croup.

The **false croup** (*laryngitis stridula*) of children usually follows a slight coryza. A harsh, hollow, ringing cough comes on, almost always suddenly and usually at night, by which the child is awakened out of sleep. The paroxysms of coughing are broken by long-drawn, noisy inspirations. The child is anxious and restless, the respiration is labored, the pulse is rapid. Such attacks recur several times during the night. The next day the child is quite lively, plays about, and has at most a slight cough. The next night, rarely sooner, the same severe attacks are repeated. After that there remains, as a rule, nothing but a slight catarrh, which completely disappears in a week or two. These sudden attacks have their origin partly in a marked swelling of the mucous membrane, occurring during sleep, partly in a neglected accumulation of secretion, and probably often also in a reflex spasm of the glottis. No other anatomical cause than a simple catarrh of the larynx is apparent, and on examining the pharynx, and, if possible, the larynx also, we find no trace of that diphtheritic process which is usually present in true laryngeal croup. It is remarkable that many children, and sometimes several children of the same family, have a specially marked predisposition to false croup. The statement, therefore, that a child has had the croup several times almost always means that it has had this form of false croup just described.

Acute laryngitis lasts only a few days in mild cases, and a week or more in severe cases. With improper care and unreasonable conduct on the patient's part an acute catarrh may run into the chronic form. We hardly ever see a fatal result in adults, even in the severe form, or in the false croup of children.

The **treatment** of acute laryngitis requires that especial attention be paid to the removal of all injurious influences. In every severe laryngitis the patient should stay in his room, and children are better off in bed. The patient should talk as little as possible. In all severe cases smoking, too, is to be forbidden. It is a good plan to furnish plenty of warm drink. Hot milk, mixed with Seltzer or Ems water, is readily taken by most patients. If there is an inhaler at our disposal, we

may let the patient inhale simple steam, or a one- or two-per-cent. solution of common salt. Inhalations of astringents are usually unnecessary. The patient may also breathe steam without any special apparatus. When there is marked irritation from coughing we may give a little morphine. With more marked local symptoms, especially if there is much pain on swallowing from swelling of the epiglottis and the mucous membrane over the arytaenoid cartilages, the patient may suck pieces of ice slowly. In severe cases of acute laryngitis, with evident symptoms of stenosis, ice must be energetically used as an internal and an external application. Sometimes, too, a few leeches applied in the region of the larynx afford distinct relief. Among external applications a mustard plaster over the front of the neck is to be recommended when there are marked local symptoms. Cold, wet compresses about the neck are also of advantage in all cases.

In the false croup of children we should use, as a rule, the same treatment as has just been described. The child should take warm drink, and a mustard paste or hot poultices should be applied to the neck. We should be rather cautious with regard to the favorite treatment with emetics, such as ipecac and sulphate of copper, although it can not be denied that they sometimes work very well.

These means are entirely sufficient for the treatment of acute laryngitis. It is only exceptionally that we find ourselves led to employ in acute laryngeal catarrh an energetic local treatment of the laryngeal mucous membrane, like painting with a 1-15 solution of nitrate of silver.

We must bear in mind that a rational hardening process is of distinct prophylactic value in persons, especially in children, with a recognized tendency to laryngitis, sore throat, etc. The best method is to bathe the neck and chest with cold water regularly morning and night.

[A mild emetic can do no possible harm in false croup, and very often cuts the attack short. The application of a sponge, moistened with water as hot as the child will bear, to the region of the larynx deserves mention.]

## CHAPTER II.

### CHRONIC LARYNGITIS.

(*Chronic Laryngeal Catarrh.*)

**Ætiology.**—Chronic laryngitis develops from an acute catarrh, or comes on gradually from the action of injurious influences on the larynx (see the preceding chapter). Chronic laryngitis, therefore, is in many cases a disease arising from the occupation, and is seen especially in singers, public speakers, criers, inn-keepers, etc. It is very frequent in drunkards, and in such cases it is almost always associated with a chronic pharyngitis. It is frequently stated that too long a uvula sets up a chronic laryngitis by constant irritation of the entrance to the larynx, and that if the uvula is amputated the disease is cured.

**Symptomatology.**—A laryngoscopic examination is very desirable in acute laryngeal catarrh, but it is the physician's absolute duty to make one in every chronic laryngitis, for only too frequently a persistent hoarseness is referred simply to catarrh when the laryngoscope gives quite another cause for it, such as paralysis of the vocal cords or new growths. Furthermore, we must always remember that a chronic laryngitis may be a complication of tuberculosis, syphilis, or chronic nephritis. On the other hand, those physicians who make a specialty

of laryngology often neglect a careful and satisfactory examination of the rest of the body when there are laryngeal troubles.

The laryngoscopic appearance in chronic catarrh may be so like that in an acute catarrh that we can not distinguish between them without the history obtained from the patient. The redness of the mucous membrane, however, is usually less intense, and the vocal cords have more of a dirty grayish-red appearance. Quite frequently in persistent catarrhs a thickening of particular parts of the mucous membrane is developed, especially of the folds between the arytaenoid cartilages. This swelling is of practical importance, because it furnishes a mechanical hindrance to the closure of the arytaenoid cartilages, and in that way contributes to the development of the hoarseness. We also find limited and marked thickening of the epiglottis, the false vocal cords (especially in public speakers and preachers), and the true vocal cords. Türk has described a peculiar form of chronic laryngitis, in which rough prominences are formed in the middle of the true vocal cords, under the name of *chorditis tuberosa*. We not infrequently find in chronic catarrh superficial erosions, especially on the true vocal cords. Superficial but very painful fissures occur upon the posterior wall of the larynx between the arytaenoid cartilages. We also very often see a disturbance of motion of one or both vocal cords, due sometimes to muscular paresis and sometimes to mechanical conditions.

The other symptoms of chronic laryngitis are hoarseness, cough, and abnormal sensations in the larynx. The hoarseness is of every degree, from mere roughness, frequent "cracking" of the voice, to almost complete aphonia. The cough is ringing, hoarse, deep, and rough. The expectoration is scanty, usually simply mucous, but sometimes a little bloody. The subjective sensations in the larynx are a feeling of burning and itching, and of dryness and tickling. They usually increase after any protracted use of the voice.

We must also mention as a very rare but practically important and peculiar form of chronic laryngitis the **chorditis vocalis inferior hypertrophica** (Gerhardt), or **laryngitis hypoglottica chronica hypertrophica** (Ziemssen). In this form there is a very gradual hypertrophy, and finally a contraction of the mucous and especially the submucous connective tissue in the inferior laryngeal space. More rarely the same changes are seen in the upper part of the larynx. The special symptom of the disease, besides a chronic hoarseness, is the appearance of a gradually increasing stenosis of the larynx. The respiration is always labored, the inspiration noisy and protracted. In many cases there are at times such attacks of suffocation that life can be prolonged only by tracheotomy. The diagnosis can be made only by the aid of the laryngoscope. We see beneath the glottis a little fissure surrounded by the thick and swollen mucous membrane of the laryngeal walls.

The precise etiology of this disease is as yet unknown. It appears to have nothing to do with syphilis, contrary to the former belief.

The **treatment of chronic laryngeal catarrh** is always a tedious and laborious task, the success of which depends in great measure upon the good will and energy of the patient. In the first place, then, we should endeavor to remove as far as possible those injurious influences which have excited and kept up the catarrh. It is often easier to give good advice here than to follow it. Nevertheless, it is the task of the physician to impress upon the patient the urgent necessity of taking care of the larynx, and to forbid as far as possible all protracted speaking, singing, staying in smoke or dust, smoking, and drinking alcoholic liquors.

Local treatment takes the second place. Among the most useful means to employ are inhalations of astringent solutions, like a one-per-cent. solution of

either tannin or alum. When there is great sensitiveness of the larynx, the patient may also inhale narcotics, a mixture of fifty parts of cherry-laurel water with a thousand parts of water, or a four-per-cent. solution of bromide of potassium. The inhalations should be used two or three times a day, and last about five minutes each time. Direct applications to the larynx are much more effective than inhalations, but these can be employed only by the aid of a laryngeal mirror. Of these we use, first of all, nitrate of silver, at first in a weak solution (one to thirty); later in a more concentrated form (one to ten, or even one to five). These applications are made every two or three days. Besides nitrate of silver, the larynx may also be painted with pure tincture of iodine, or with iodine and glycerine, or with concentrated solutions of alum or tannin. Where the secretion of mucus is considerable, benefit will be obtained from inhalations of turpentine, or of *oleum pini* or *oleum pini pumilionis* (P. G.).

Water-cures are also often prescribed in chronic catarrh of the larynx. These are so far of advantage that, from the greater care which the patient takes, and from the good air, the catarrh improves. Empirically, we prescribe, especially for "full-blooded" patients, the cold sulphur springs, like Nenndorf, Eilsen, or Weilbach, or the sulphate of sodium waters, like Carlsbad and Marienbad, while we send those of delicate constitutions to Ems, Salzbrunn, Salzgungen, Reichenhall, or Ischl.

The treatment of laryngitis hypertrophica, when it leads to stenosis, must be mechanical. Schrötter, in particular, has devised several methods in order to dilate the stenosis gradually by the introduction of bougies and harder dilators. The details of this treatment are to be found in the later special works referred to above.

### CHAPTER III.

#### LARYNGEAL PERICHONDritis.

**Ætiology and Pathological Anatomy.**—The inflammation of the perichondrium of the laryngeal cartilages is in very rare cases apparently a primary disease. It is much more frequently secondary to other laryngeal affections, especially tuberculosis and syphilis of the larynx. Furthermore, it develops secondarily in severe acute diseases, most frequently in typhoid fever, more rarely in small-pox, diphtheria, etc. Superficial ulcerative processes in the mucous membrane often precede the perichondritis in these cases, and the participation of the perichondrium in the inflammation arises from their gradual deepening. Anatomically, we have to do as a rule with a purulent inflammation, which usually leads to the formation of circumscribed abscesses. Most laryngeal abscesses have their origin in the perichondrium.\* The perichondrium is in part destroyed by the abscess and in part elevated from the cartilage. The cartilage then becomes necrotic, breaks in pieces, and is expelled in small particles or in masses.

Perichondritis occurs most frequently in the cricoid and arytaenoid cartilages, much more rarely on the internal or external surface of the thyroid cartilage. Hence we distinguish an internal and an external perichondritis. A perichondritis of the epiglottis has also been repeatedly observed.

**Symptomatology.**—In the rare cases of primary perichondritis, marked laryngeal symptoms are speedily developed in a person previously healthy. These

\* Pure submucous abscesses, the so-called phlegmonous laryngitis, occur only in very rare cases.

symptoms are pain and tenderness on pressure over the larynx, hoarseness, and cough; and to them are usually soon added the signs of a dangerous stenosis of the larynx. In secondary cases, which occur almost always in patients who are already seriously ill, the symptoms of stenosis are often the first to point to a severe disease of the larynx. On laryngoscopic examination, besides the general redness and swelling in particular places, we can sometimes recognize a circumscribed protrusion of the mucous membrane caused by the abscess. We often find, besides, a considerable collateral œdema of the surrounding mucous membrane, which œdema frequently has a greater share in the production of stenosis than has the primary affection itself. The dreaded œdema of the glottis (œdema of the ary-epiglottic ligament) in typhoid, tuberculosis of the larynx, etc., is usually due to perichondritis of the cricoid or arytenoid cartilages. Finally, we can see with the laryngoscope, especially in perichondritis arytenoidea, a considerable disturbance of motion of the affected arytenoid cartilage, and also of the vocal cords. In the later stages, if the abscess has been opened, or if it breaks of its own accord, and the whole cartilage or a part of it is expelled, we can make out the extent of the destruction that results more accurately by the laryngoscope.

Laryngeal perichondritis terminates fatally in a great number of cases from the development of stenosis. In other cases the most threatening symptoms may be averted for a time, but the primary disease, such as tuberculosis, finally comes to an unfavorable termination. In the rare cases in which recovery occurs after primary perichondritis or after the termination of the primary disease, such as typhoid, this recovery is often incomplete, since a chronic stenosis of the larynx remains from the ensuing cicatricial contractions.

The **diagnosis** is usually obscure during the first period of severe symptoms of stenosis, since it is difficult to make a laryngoscopic examination, and it is also not always easy to determine the condition. We are usually justified, however, in making the diagnosis, if in those diseases which we have mentioned, in which we know by experience that a perichondritis quite frequently occurs, the danger of suffocation arises in addition to the other laryngeal symptoms. It is of practical importance to recognize stenosis of the larynx with certainty, for it demands a speedy therapeutic interference.

**Treatment.**—In the beginning of the affection we may try to reduce the inflammation by the internal and external application of ice or by leeches; but if stenosis of the larynx occurs, surgical interference is usually necessary, for only in very rare cases do we see the abscess open of itself and a subsidence of the dangerous symptoms follow. In the majority of cases the patient can be saved from suffocation only by the timely performance of tracheotomy. The laryngeal abscess has been repeatedly opened internally by laryngologists with favorable results. If a chronic stenosis of the larynx remains after a favorable termination of the disease, either the patient must wear a tracheal canula all his life, or the attempt may be made to dilate the stenosis gradually by the methods referred to in the preceding chapter.

#### CHAPTER IV.

#### CEDEMA OF THE GLOTTIS.

THE practical importance of the subject demands a brief special description of œdema of the glottis, by which name we mean œdema of the entrance of the larynx, especially of the ary-epiglottic ligaments. We have already learned to recognize laryngeal perichondritis as one of its most frequent causes. In less

deeply seated inflammations in the larynx and its neighborhood, however, œdema of the glottis may sometimes develop as a dangerous complication, especially in cases of laryngitis occurring in the course of severe acute diseases, like typhoid, small-pox, or erysipelas, or in inflammations of the larynx arising from severe mechanical or chemical irritation, like hot steam or corrosive substances, or from wounds of the larynx, or, finally, from foreign bodies in the larynx. The col-lateral œdema in angina Ludovici, in intense inflammations of the parotid gland, or the tonsils, etc., may in rare cases extend to the ary-epiglottic ligaments. Finally, œdema of the glottis occurs in rare cases as a complication of general œdema of the body, as a result of Bright's disease, disease of the heart, emphysema of the lungs, etc. Œdema of the glottis has been repeatedly observed to come on quite suddenly, especially in Bright's disease.

The chief symptom of œdema of the glottis is dyspnœa, which comes on as a result of the stenosis of the entrance of the larynx, and is sometimes extreme. At first this is chiefly on inspiration, but it soon comes on with expiration also. Respiration, especially inspiration, is accompanied by a loud laryngeal stridor. As a result of the incomplete entrance of the air, the efforts at inspiration involve the neck, the epigastrium, and the sides of the thorax. We see with the laryngoscope, if the examination be successful, an œdematous swelling of the ary-epiglottic ligaments, and often a swelling of the epiglottis and the false vocal cords. Sometimes we succeed in feeling the swollen parts with the finger.

If the dyspnœa reaches a degree which threatens life, an operation is the only thing which can afford relief. Laryngologists attempt to reduce the swelling by long incisions in the œdematous parts. If this does not succeed, tracheotomy must be performed. If the immediate danger to life is thus averted, further treatment should be directed to the disease which has given rise to the œdema.

## CHAPTER V.

### TUBERCULOSIS OF THE LARYNX.

(*Laryngeal Phthisis. Consumption of the Larynx.*)

**Ætiology.**—Since tuberculosis of the larynx is in most cases combined with tuberculosis of other organs, especially of the lungs, we must refer to the description of tuberculosis of the lungs for the general ætiology and pathology of the disease. A particular description of the special appearances in laryngeal tuberculosis, is, however, justifiable, because tuberculosis may at times begin in the larynx and may remain isolated there, at least for a time; and, furthermore, in many cases of laryngeal tuberculosis, which are evidently combined with pulmonary tuberculosis, the laryngeal symptoms are predominant in the clinical picture of the disease. Many physicians have, wrongly as we think, disputed the fact that tuberculosis can begin in the larynx. Clinical experience not infrequently teaches us that men, who up to that time were apparently in good health, are attacked with hoarseness, the disease being at first thought to be a common laryngitis, but at last, by its later course, proving to be a tuberculosis. In spite of the most careful examination, there are not to be found at first the slightest physical signs of disease in the lungs, and not till later do the manifest signs of a pulmonary tuberculosis succeed the symptoms of a laryngeal affection. In such cases it seems to us an affectation to claim that there is a primary pulmonary tuberculosis which could not be made out at first. Everything is much more in favor of the opinion that the tubercular poison, the tubercle bacilli, may sometimes first

fix upon the larynx, excite the first symptoms of tuberculosis there, and only later attack the lungs.

In the majority of cases of laryngeal tuberculosis the symptoms are developed, of course, secondarily in the course of chronic pulmonary phthisis. We shall see that in these cases the disease of the larynx is to be considered as the result of an infection of the mucous membrane of the larynx by the tuberculous sputum which passes over it. In about one fourth of all cases of pulmonary tuberculosis this complication occurs, if we include all the mild diseases of the larynx. Marked and extensive tuberculosis of the larynx is much rarer, however.

**Pathological Anatomy.**—In its anatomical appearances the laryngeal affection which complicates pulmonary phthisis or occurs primarily is at first usually a simple catarrh of the mucous membrane, which does not differ in any remarkable way from any other laryngeal catarrh. Shallow erosions, too, on the vocal cords or between the arytenoid cartilages have nothing characteristic in themselves. In fact, it is even hard to decide whether the simple laryngeal catarrh and superficial ulcers in the larynx, which often occur in phthisical patients, are really in every case specific tubercular affections. Perhaps they are often only the result of the mechanical irritation from the frequent cough or of the chemical irritation from the sputum. This question is to be decided finally only by the discovery of the special tubercle bacilli in the laryngeal affections of phthisical patients.

The more marked changes in the larynx in phthisical patients, however, are without doubt always of tubercular origin. In these we find a characteristic tubercular infiltration, with the formation of miliary tubercles in the mucous and submucous tissues. When the infiltrated parts break down, extensive ulcers are formed which always extend farther, and whose favorite seat is on the arytenoid cartilages, the vocal cords, and the epiglottis. From the latter the ulcers not infrequently extend to the back of the tongue. In severe cases we often find a marked collateral oedema in the neighboring parts accompanying the inflammation, and sometimes the tubercular perichondritis which has already been described.

**Clinical Symptoms.**—In the beginning of tuberculosis of the larynx the laryngoscope usually shows nothing but the appearances of a simple catarrh. In the later stages, however, most of the special signs of the destructive tubercular process, like ulcers, infiltration, etc., can be very satisfactorily made out. In fact, we often get in this way a better picture of the disease than we do at the autopsy, for the hyperæmia and swelling of the parts are much diminished in the cadaver.

The other clinical symptoms of tuberculosis of the larynx vary very much with the extent and intensity of the process. Sometimes they consist merely in moderate roughness and hoarseness of the voice, but in other cases they increase to the most painful condition which is ever seen in any variety of tuberculosis. This is especially apt to be the case if the ulceration involves the epiglottis and the arytenoid cartilages. Swallowing is then extremely painful, so that the nutrition is very often impaired, and painful attacks of coughing frequently occur. If severe ulcerations attack the vocal cords, and their free mobility is affected to a marked degree, the hoarseness increases, and finally reaches a complete aphonia. Death finally occurs from general inanition, or, exceptionally, from oedema of the glottis.

The diagnosis of tuberculosis of the larynx is not difficult if pulmonary phthisis is already known to be present. When attention has been called to it from the onset of hoarseness or from some disturbance in swallowing, we recognize

the character and seat of the changes by the aid of the laryngoscope. The diagnosis, however, may present much difficulty in cases where we are not sure that an affection of the lungs co-exists. As has been said, the symptoms at first are not unlike those of a simple catarrh, and the suspicion of the existence of tuberculosis is first aroused from the stubbornness of the disease, the condition of the patient, some inherited taint, the onset of fever, and the remarkable emaciation. With the changes in the larynx which have been described the distinction between tuberculosis and syphilis may be very difficult. In syphilis of the larynx, however, we find that co-existing changes in the pharynx are much commoner than in tuberculosis, and the cicatricial formation which is usually visible furnishes, besides, a very characteristic evidence of syphilis. The diagnosis of tuberculosis of the larynx, however, is made perfectly certain in all doubtful cases by the discovery of tubercle bacilli in the patient's expectoration or in the secretion from the ulcer, which often can be easily obtained by the aid of a fine laryngeal brush. In regard to the laryngoscopic appearances, we may also say that a thick infiltration of the epiglottis with a partial ulceration of the same is an appearance which is almost exclusively confined to tuberculosis. The same is true with regard to a marked projecting infiltration of the inter-arytænoïd region.

For the general *treatment* of tuberculosis the reader is referred to the consideration of pulmonary tuberculosis. We shall here discuss merely the local treatment. This is in the milder forms the same as for simple laryngeal catarrh. There is no doubt that even genuine tuberculous ulceration of the larynx may be healed. Nevertheless permanent cures of this sort are exceptional. Of course very much depends upon the general condition of the patient, and upon the co-existing state of the lungs. For local treatment insufflations of iodoform and iodol were for a time strongly recommended, but they are now for the most part abandoned. Of late the best results, comparatively speaking, have been reported from the local employment of lactic acid, in a solution of thirty per cent. to eighty per cent. and preceded by cocaine, and of menthol in a twenty-per-cent. solution in oil. But all these methods of treatment demand considerable dexterity. Inhalations are for the most part merely palliative. We have always obtained the best satisfaction in this regard from inhalations of Peruvian balsam. It is our conviction that for any true advance in the treatment of laryngeal tuberculosis we must look to surgery, and not to endo-laryngeal manipulations, which are always unsatisfactory even in the best hands, but to a complete excision of the diseased tissue by means of laryngotomy. In advanced cases it will usually be found advisable to employ merely palliative treatment.

The constant use of cracked ice, and especially a lavish employment of narcotics, form the best means of lessening the pain and the difficulty in swallowing. Subcutaneous injections of morphine a quarter of an hour before each meal often afford great relief. Besides this, we can paint the larynx with strong solutions of morphine, blow in powdered morphine, or let the patient inhale solutions of morphine or bromide of potassium. Cocaine, which is an excellent local anæsthetic, excels all these, however, in potency (von Anrep). If we paint the ulcerated mucous membrane at the entrance of the larynx with a ten- or twenty-per-cent. solution of cocaine, in a few minutes such an anæsthesia of the affected parts ensues that swallowing may take place without any pain. The following formula may be used:

R Cocaini muriatis.....	gr. xv-xxx	(1·0-2·0);	
Alcohol.....	3 ss	(2·0);	
Aquæ destillatæ .....	3 ij	(8·0).	M.

Unfortunately, the action of cocaine is extremely transitory, so that the painting must be repeated over and over again.

## CHAPTER VI.

### PARALYSES OF THE LARYNGEAL MUSCLES.

**1. Paralysis in the Distribution of the Superior Laryngeal Nerve.**—The superior laryngeal nerve, arising from the vagus, is the sensory nerve for the mucous membrane of the upper portion of the larynx down to the glottis, and also for the mucous membrane of the epiglottis and its neighborhood. Besides this, it also supplies motor fibers to the crico-thyroid muscle. Clinical experience renders it probable that the superior laryngeal nerve also supplies the depressors of the epiglottis, the thyro-epiglottideus, and the aryteno-epiglottidei muscles, and perhaps also the arytenoideus muscle. The last three muscles mentioned, however, perhaps derive some motor fibers from the recurrent nerve also (the inferior laryngeal nerve).

Paralysis of the crico-thyroid muscles and of the depressors of the epiglottis is seen most frequently after recovery from diphtheria. It is usually a part of a more extensive paralysis, and, in addition, is frequently associated with anaesthesia of those parts of the mucous membrane which, as we have seen, derive their sensory fibers from the superior laryngeal nerve (von Ziemssen).

Paralysis of the thyro-epiglottideus and the aryteno-epiglottidei muscles is recognized by the immobility and the erect position of the epiglottis, which is directed toward the back of the tongue.

Paralysis of the crico-thyroid muscles makes the voice rough, and especially renders the production of high tones impossible, since for this purpose we need the action of this muscle as a tensor of the vocal cords. The detection of this paralysis by the laryngoscope is extremely difficult. Its chief signs are a concavity of the edges of the vocal cords, a lack of visible vibration in them, and perhaps, in unilateral paralysis, a higher position of the vocal cord on the sound side.

For paralysis of the arytenoideus muscle, *vide infra*.

**2. Paralysis in the Distribution of the Inferior Laryngeal or Recurrent Nerve.**

—The recurrent nerve supplies with sensory fibers the mucous membrane of the inferior cavity of the larynx below the glottis, and it is the motor nerve for all the laryngeal muscles except the crico-thyroid, and except possibly the depressors of the epiglottis (*vide supra*). The muscles innervated by it are arranged according to their function in the three following groups:

- a. The openers of the glottis—the posterior crico-arytenoid muscles alone.
- b. The closers of the glottis—the lateral crico-arytenoids and the arytenoideus (transverse and oblique).
- c. The tensors of the vocal cords—the thyro-arytenoids, which act usually as closers of the glottis, but which very often produce the fine differences in tension in the vocal cords which are necessary in singing and in modulations of speech. They accordingly have the same task as the coarser-working crico-thyroid muscles, which are innervated by the superior laryngeal nerve.

The motor fibers for all these muscles have their special origin in the accessory nerve, from which they pass into the trunk of the vagus, and from this into the laryngeal nerves.

Most of the paralysees of the recurrent nerve are of peripheral origin. Except

in the pure muscular pareses (*vide supra*), which arise not infrequently in the course of other laryngeal affections, peripheral paralyses of the vocal cords occur with the greatest relative frequency from an abnormal pressure on the trunk of the recurrent nerve, especially in aneurism of the arch of the aorta, which may cause a left-sided paralysis. Tumors of the bronchial glands, cancer of the œsophagus, thyroid or mediastinal tumors, and, in rare cases, even large pericardial effusions, may also cause a paralysis of the recurrent on one side. Paralyses on the right side are seen quite frequently in contractions at the apex of the right lung and in the rare cases of aneurism of the subclavian artery. The paralyses of the laryngeal muscles, which are sometimes met with after recovery from diphtheria (*q. v.*), also belong to the peripheral paralyses of the recurrent nerve, and their cause is to be found in a degeneration of the branches of the affected nerves. In other cases the paralysis of the recurrent nerve is due to an affection of its fibers in the vagus or even in the accessorius. Excluding certain injuries from operations, these affections are usually due to new growths which cause a paralysis of conduction. Paralyses of the recurrent nerve also arise from affections of the nucleus of the accessory nerve in diseases of the medulla, in the different forms of acute bulbar paralysis, in chronic bulbar paralysis, in multiple sclerosis, etc. The frequent hysterical paralyses in the distribution of the recurrent nerve are to be regarded as cerebral. Finally, paralyses of the laryngeal muscles are sometimes observed for which we are not in a position to find any cause.

**1. Complete Paralysis of the Recurrent Nerve.**—Paralysis of all the laryngeal muscles supplied by the recurrent nerve occurs quite frequently in the pressure

FIG. 14.—(From ZIEMSEN.) Position on inspiration in paralysis of the left vocal cord, or paralysis of conduction in the recurrent nerve.

paralysis of the trunk of the recurrent, or of its fibers in the vagus. With the laryngoscope (see Fig. 14) we find the vocal cord on the paralyzed side in a middle position, often falsely called a "cadaveric position," and completely motionless on respiration, and also on phonation. On phonating as strongly as possible, the vocal cord on the sound side passes beyond the median line, the arytenoid cartilage also crosses the line, and consequently the glottis is put in an oblique position. The other symptoms are sometimes so slight that without a laryngoscopic examination we do

not even think of a paralysis. The speech, however, is usually not pure; it often breaks into a falsetto, and the patient is easily tired by speaking. With bilateral paralysis of the recurrent nerve, which is very rare, we find both vocal cords motionless in a middle position. Complete aphonia exists, and it is impossible to cough, since in coughing we have to make at first a complete closure of the glottis. There is no dyspnoea, however, if the patient keeps quiet.

**2. Paralysis of the Dilators of the Glottis, the Posterior Crico-arytenoid Muscles.**—Bilateral paralysis of these muscles is a very rare phenomenon, but clinically it is of the utmost importance, since it results in a condition of most marked inspiratory dyspnoea. This condition develops gradually, and usually without any cause that has been satisfactorily determined. There is probably some affection of the nerves themselves which finally leads to the paralysis.\* In most cases the disease lasts for years. The dyspnoea may increase, especially from external causes, to severe attacks of suffocation, and tracheotomy is frequently

\* It is remarkable, however, that a purely mechanical hindrance to the dilatation of the glottis may occur from the formation of ankylosis in the crico-arytenoid articulation.

necessary. In paralysis of the dilators of the glottis the respiration is so changed that inspiration only is difficult, protracted, and noisy, while expiration is free and unhindered. This depends on a valve-like action of the vocal cords. They are drawn together by the dilatation of the thorax on inspiration, while the current of air in expiration easily pushes them aside. Phonation is usually entirely undisturbed. With the laryngoscope (see Fig. 15) we find the glottis changed to a small slit, which grows narrower instead of wider on inspiration.

The prognosis is usually unfavorable. Only in the hysterical can these apparently severe conditions appear and disappear again in a short time.

### 3. Paralysis of the Thyro-arytænoid Muscles.—

The paralysis or paresis of these muscles, which run into the vocal cords, and which are their chief tensors, is one of the most frequent of the paralyses of the laryngeal muscles. It occurs especially in acute and chronic catarrh of the laryngeal mucous membrane, and is often the chief cause of the accompanying hoarseness. It also frequently develops as the result of an habitual over-exertion of the voice in singers and public speakers, and it is one of the commonest causes of hysterical aphonia.

Paralysis of the thyro-arytænoid muscles may be bilateral or unilateral. It is frequently associated with a paresis of the other closers of the glottis, the arytenoidei and the crico-thyroid muscles. With the laryngoscope (see Fig. 16), in the ordinary bilateral paresis of the thyro-arytænoid muscles, we see that on phonation the glottis does not close completely, but that an oval space is left between the vocal cords.

In unilateral paralysis the affected cord shows a concavity of its edge. The voice is always more or less hoarse and low and the speech is strained.

In many cases, after a cure of the original catarrh, a complete recovery from the paralysis may follow by taking good care of the voice. Hysterical paralyses are diagnosticated by their sudden disappearance and reappearance, usually after some psychical disturbance. They are quite common in children of the age of ten to fourteen years, especially in girls. (See the chapter on hysteria.)

4. **Paralysis of the arytenoideus muscle** is rarely an isolated phenomenon. It is sometimes seen in laryngeal catarrh or in hysterical aphonia. The voice is

FIG. 16.—(FROM ZIEMSEN.)—Paralysis of both internal thyro-arytænoid muscles in the course of an acute laryngitis.

quite hoarse, and with the laryngoscope (see Fig. 17) we find on phonation that the whole anterior part of the vocal cords closes well, but that the cartilaginous glottis remains open as a triangular gap on account of the imperfect motion of the arytenoid cartilages toward each other. When the thyro-arytænoids are paralyzed with the arytenoideus, the glottis shows on phonation a narrow hour-glass opening (see Fig. 18). Both the anterior and the posterior portions of the glottis fail to close, while the vocal processes take their usual median position on phonation from the normal turning of the arytenoid cartilages inward by the action of the lateral crico-arytænoid muscles.

5. **Paralysis of the lateral crico-arytænoid muscles**, as an uncomplicated condition, has never been observed with certainty. Some cases of a complete and simultaneous paralysis of all the closers of the glottis have been described, however, in which the vocal cords are immovable laterally and the glottis remains abnormally wide open.

FIG. 15.—(FROM ZIEMSEN.)—Complete bilateral paralysis of the posterior crico-arytænoid muscles at the moment of inspiration.

We may expect success from the **treatment** of paralysis of the vocal cords only when the primary disease is capable of cure. If catarrhal or other diseases of the

FIG. 17.—(From ZIEMSEN.) Paralysis of the arytaenoids in acute laryngitis.

FIG. 18.—(From ZIEMSEN.) Bilateral paralysis of the thyro-arytaenoids combined with paresis of the arytaenoids.

larynx co-exist, we must first treat these by the methods already mentioned. Paralysis from the compression of tumors, etc., may be relieved in rare cases by extirpation, or by partial resolution of the tumors when of strumous origin. In catarrhal, diphtheritic, and the so-called "rheumatic" pareses—that is, those which occur without any assignable cause—and also in all hysterical aphonias, electricity often works very well. A very rapid recovery sometimes occurs in hysterical paralyses, but it is not always permanent. We commonly employ external faradization of the neck or galvanization through the larynx, combined with frequent changes of the current. Ziemssen has made electrodes for the endolaryngeal irritation of single muscles. Internally we may prescribe preparations of iron and small doses of quinine, especially in anæmic patients. Subcutaneous injections of strychnine are also of advantage, in doses of gr.  $\frac{1}{8}$  to gr.  $\frac{1}{4}$  daily (grm. 0.003 to 0.01). Methodical efforts at speaking and breathing are of great service in hysterical aphonia.

## CHAPTER VII.

### SPASM OF THE GLOTTIS.

(*Millar's Asthma. Thymic Asthma.*)

**Ætiology.**—Spasm of the glottis is a disease which occurs almost exclusively in children under three years of age, and which consists of attacks of spasmodic closure of the glottis, and consequently of most severe dyspnoea. Boys are more frequently attacked by this disease than girls, but the cause of this is wholly unknown. The old name of thymic asthma arose from the idea that the attacks were due to an increase in the size of the thymus gland, but this opinion is wholly unfounded. The relation between spasm of the glottis and rachitis is remarkable, but it is unexplained. Nearly two thirds of all the children who suffer from spasm of the glottis are rachitic, but the opinion which was once held that spasm of the glottis has a special relation to the rachitic craniotabes is not clearly proved. The fact that it is often combined with eclampsia, in that the attacks of spasm of the glottis are aggravated by eclamptic attacks, and that the two alternate with each other, is an argument in favor of a central origin for the disease. In the cases which come on, as they often do, at the time of dentition, we think it possible to assume a reflex origin for the spasm, just as we may in those cases which seem to follow a laryngitis due to taking cold.

**Symptomatology.**—The single attacks usually come on suddenly by day or by

night, either without any cause or from some external influence, like crying, swallowing fluid, or some psychical disturbance. They usually begin with a deep inspiration, followed by complete cessation of respiration. The child becomes pale, cyanotic, looks anxiously about, rolls his eyes, and makes strained and labored efforts at respiration. In severe cases there is a temporary loss of consciousness, and tonic and clonic spasms in the muscles of the extremities and the trunk, as has been mentioned. The attack lasts from some seconds up to two minutes. In very severe cases the attack may be immediately fatal. As a rule, however, the spasm passes off, deep, noisy inspirations follow, and in a short time the child is completely well. The severity of the attacks varies, moreover, in different cases, and it varies very markedly, too, in the same child. Sometimes we have only one attack or a small number of them, while in other cases they may come on ten or twenty times a day, and even oftener, and may last with varying intensity for months. If the child reaches his third year the disease almost always disappears, but quite a large number of the children who suffer from spasm of the glottis die before that age, either in the attack itself or from other affections.

Pure spasm of the glottis hardly ever occurs in adults, but similar attacks are sometimes observed in hysteria.

The **treatment** must be especially directed to the child's general condition. The child is usually pale and emaciated, and if we succeed in improving its nutrition with iron and cod-liver oil, the attacks become less frequent, milder, and finally may wholly disappear. The child should also be kept in moderately warm air and guarded from any exposure to cold. Internal remedies to prevent the recurrence of the attacks are very uncertain in their action. We may employ bromide of potassium, ten to thirty grains daily (grm. 0.5-2.0); musk, ten drops of the tincture every hour or two; oxide of zinc, etc.

In the attack itself the child must be raised up. The face should be sprinkled with water, or, if the attack be of long duration, a cool shower-bath should be given. Friction should be applied to the skin, aided by mustard, or a mustard plaster to the chest and calves. If the attacks are very frequent and intense, we must use narcotics, either inhalations of chloroform or subcutaneous injections of morphine, with care, in doses for a child of  $\frac{1}{8}$  to  $\frac{1}{12}$  of a grain (grm. 0.001 to 0.005).

## CHAPTER VIII.

### DISTURBANCES OF SENSIBILITY IN THE LARYNX.

DISTURBANCES of sensibility in the laryngeal mucous membrane have been observed especially in the distribution of the superior laryngeal nerve, in the epiglottis, and in the superior cavity of the larynx above the glottis; but in rare cases they are also observed in the lower portion of the larynx, which is supplied with sensory fibers by the recurrent nerve. They are most frequently associated with motor disturbances, particularly with hysterical paralyses, but they are also quite often found in paralyses of diphtheritic origin. Anæsthesia of the larynx is recognized by the lack of sensation which the patient shows when we touch special parts of the larynx with the point of a sound. The choking and coughing reflexes are almost always absent, so that we can touch the whole entrance of the larynx with the finger without causing discomfort.

The absence of the reflexes may sometimes be dangerous, especially in severe diphtheritic and bulbar paralyses, for, as a result of it, small portions of saliva may

reach the larynx in swallowing, and fail to be coughed up, but may be drawn down into the lungs, where they set up a bronchitis and a lobular pneumonia. This danger is especially great if at the same time the patient can not cough forcibly, as is frequently the case in imperfect closure of the glottis. Hysterical anaesthesia is the only form where there is no fear of the development of inhalation diseases in the lungs.

An effective prophylaxis against the dangerous condition just described is possible only by feeding patients, who have much weakness in swallowing and coughing, by means of the oesophageal tube.

## CHAPTER IX.

### NEW GROWTHS IN THE LARYNX.

SINCE new growths in the larynx are of interest rather to specialists and surgeons, we will here only glance briefly at them. We must remember especially, however, that they can be recognized only by the aid of the laryngoscope. It unfortunately often happens that a patient is treated for a long time without success for a "chronic laryngeal catarrh," until the laryngoscope finally shows that a new growth is the cause of the hoarseness. It is of especial importance, however, to make a diagnosis as early as possible, particularly in carcinoma, since the earlier the operation is done the better is the chance for success (*vide infra*).

#### A. BENIGNANT NEW GROWTHS IN THE LARYNX.

1. Papilloma is one of the commonest new growths in the larynx. It forms glandular, cauliflower-like excrescences, which are usually situated on the anterior part of the vocal cords, rarely on the false cords. The base of the swelling is broad or pediculated. We do not know the special cause of their origin. They sometimes develop upon an existing chronic catarrh.

2. Fibroma in the larynx is comparatively common. The tumors known as "laryngeal polypi" are usually fibromata. They are generally situated on the

FIGS. 19 and 20.—(From ZIEMSEN.) Pediculated fibromata.

vocal cords and form whitish or reddish-brown swellings, from the size of a pea to that of a cherry, and are usually pediculated (see Figs. 19 and 20). People who use their voices very much are especially liable to the formation of fibromata.

3. Cysts and "mucous polypi" rarely occur. They are probably due to the retention of the secretion in a mucous gland from the stoppage of its orifice. We find them in the ventricles of Morgagni, on the epiglottis, etc.

The symptoms which are excited by benignant tumors in the larynx depend partly upon the situation and partly upon the size of the new growth. Small polypi may exist wholly without symptoms, and are found only by chance on

laryngoscopic investigation. Usually, however, the presence of hoarseness, pressure, and itching in the larynx, or respiratory disturbances, when the tumor is a large one, are the symptoms which give occasion for an examination.

#### B. MALIGNANT NEW GROWTHS. CARCINOMA OF THE LARYNX.

Carcinomata develop usually in old people, either primarily in the larynx or secondarily from affection of the neighboring organs. In the first case the vocal cords or the ventricles of Morgagni are the points most frequently attacked. An extension of the disease to the larynx is seen especially in cancer of the tongue or pharynx, rarely in cancer of the œsophagus.

The symptoms of cancer of the larynx develop slowly. Hoarseness, disturbance in swallowing, pains in the larynx often shooting up into one ear, the appearance of respiratory symptoms, and finally the signs of general weakness and emaciation which are seen in almost all forms of carcinoma, form the picture of the disease. The diagnosis is possible only by the aid of the laryngoscope. Besides this, a digital examination may at times be of diagnostic value by the detection of the characteristic hardness about the entrance or in the neighborhood of the larynx. A general description of the laryngoscopic appearances can not be given on account of the diverse character of the cases. We see the uneven, injected new growth, covered with mucus and often ulcerated, and besides this at times the secondary appearances of catarrh, a developing perichondritis, etc. With a little care the diagnosis is usually tolerably easy. It may be difficult, however, at times, to distinguish it from tuberculosis or from syphilis. We may be aided in such cases by the discovery of the tubercle bacilli or by the results of anti-syphilitic treatment. All the other organs of the patient therefore must always be carefully examined.

Surgical **treatment** is the only one for all laryngeal new growths. We must refer to the special works for all the details. Laryngologists have devised numerous instruments for the removal of benignant polypi, by which, under the guidance of the laryngoscope, the new growth is cut, snared, squeezed, or torn off. The performance of the operation is made much easier by the advantage of the local anaesthesia of the laryngeal mucous membrane due to painting with cocaine (see p. 138). Nevertheless we firmly believe, about these growths as well as about tuberculosis of the larynx, that the "endolaryngeal" operations should be more and more superseded by laryngotomy.—Carcinoma of the larynx can be cured only through removal of the tumor by splitting the larynx or by its total extirpation. The former operation is comparatively free from danger, while total extirpation has met with success as yet in but few instances. If surgical interference is no longer practicable, we can only endeavor to mitigate the suffering of the patient by means of morphine, cocaine, and other narcotics.

---

## SECTION III.

*DISEASES OF THE TRACHEA AND THE BRONCHI.*

## CHAPTER I.

**ACUTE CATARRH OF THE TRACHEA AND THE BRONCHI.***(Tracheitis and Acute Catarrhal Bronchitis.)*

**Ætiology.**—Acute catarrh of the larger air-passages, of the trachea, and larger bronchi, is a frequent disease, and it may often arise from taking cold. It is conceivable that the inhalation of cold, damp air sometimes directly affects the mucous membrane of the upper air-passages. Bronchial catarrh is very often associated with a coincident catarrh of the larynx, and more rarely of the pharynx. In the ordinary mild forms the catarrh is usually confined to the trachea and the first large branches of the bronchi, while the finer bronchi remain healthy.

More intense inflammation of the bronchial mucous membrane is the result of active mechanical or chemical irritation. A severe bronchitis develops after the inhalation of noxious gases, nitrous and sulphurous oxides, chlorine, bromine, etc., as is often observed in operatives. The inhalation of smoke and dust, especially vegetable dust, works in the same injurious fashion, and the followers of many trades and employments, like millers, colliers, etc., are especially subject to disease from this cause. In this form of bronchitis the catarrh often extends to the finer bronchi.

The bronchitis which develops in the course of other acute and chronic diseases is still commoner than the primary forms already mentioned. It is often due to infectious causes, like certain infectious diseases, especially measles, whooping-cough, and influenza. In these diseases bronchitis is one of the most constant local affections, and is probably immediately dependent upon the primary infection. Bronchitis, however, develops secondarily in most of the other acute infectious diseases, and is largely due to the inhalation of noxious substances from the upper part of the air-passages. This is the explanation of the bronchitis in diphtheritic processes in the pharynx and larynx, in so far as it does not depend upon a direct extension of the disease, and also of the bronchitis in small-pox, etc. Bronchitis may also be met with in all other forms of severe disease, because retention of secretion, inflammation, thrush, etc., arise in the cavity of the mouth and pharynx, and from them chemical or organic irritants may easily be inhaled into the bronchi. The imperfect expectoration in all severe diseases is a still more harmful factor than this inhalation. The secretion remains in the bronchi, processes of decomposition arise in the stagnating mucus, bacteria collect and lead to a bronchitis, and finally to a lobular pneumonia which is so often found (*vide infra*). The swallowing and inhalation of portions of saliva, which easily decompose, is also a frequent cause of secondary bronchitis.

We do not know how far we may claim that infectious agents act as a cause of primary bronchitis, yet it is not improbable that many cases have such an ætiology. It is especially likely that many cases of bronchitis due to "catching cold" really have something infectious about them, and that the preceding exposure to cold has merely lowered the natural powers of resistance, and thus permitted, or at any rate promoted, infection.

Finally, we must mention that an acute bronchitis is sometimes merely an exacerbation of a previous chronic bronchitis.

The predisposition to acute bronchitis varies in different persons. We do not

know definitely on what ground such an increased predisposition to bronchial disease rests, nor why we meet with it sometimes in the weak and anæmic, and at other times in the so-called "full-blooded" persons. Bronchitis is more frequent in children and old people than in those in middle life. Most of the cases occur in the spring and autumn.

**Symptoms.**—Pain in the chest may be present in some cases of simple catarrhal bronchitis, but usually only in a moderate degree. In severe tracheitis patients often have a painful feeling of soreness in the neck and behind the upper part of the sternum, and this is increased on coughing. The mucous membrane of the bronchi, apparently, has no nerve-fibers which are sensitive to pain, and the pains in the chest which are often present in bronchitis are, as a rule, muscular pains in the intercostal muscles, due to the severe paroxysms of coughing.

Cough is one of the most constant symptoms of bronchitis, and by it usually the attention of the patient or of the physician is first called to the existing thoracic affection. The cough may of course be due to a laryngitis, if that is also present. There is no doubt, however, but that a cough may be excited in a reflex manner from the mucous membrane of the trachea and of the larger as well as of the finer bronchi. Experiments have shown that the point of bifurcation of the trachea is especially irritable, and many severe paroxysms of coughing may be due to an irritation of this very spot from the accumulation of secretion. The intensity of the cough, moreover, is very different in individual cases, which is due in part to the degree and extent of the bronchitis and in part to the reflex irritability of the person affected.

The expectoration consists of the secretion from the inflamed mucous membrane. Its abundance and consistency vary very much in the different cases. We distinguish a catarrh with an abundant secretion, and the so-called "dry catarrh." In the latter only a little viscid sputum is expectorated, but in the former the expectoration is more abundant and muco-purulent. Very often in the beginning of the disease the expectoration is scanty and viscid—the *sputum crudum* of the old physicians; and later it becomes more abundant, more fluid, and more purulent—the *sputum coctum*. In catarrh of the finer bronchi the expectoration may contain little mucous or muco-purulent casts of the bronchi. A simple catarrhal expectoration shows nothing peculiar under the microscope. The pus-corpuscles are often swollen, and show more or less marked fatty degeneration. A slight admixture of blood may occasionally be present in severe bronchitis, but it usually has no special significance, being at times merely the result of severe fits of coughing. A more marked and persistent admixture of blood is seen in the catarrhal sputum in some cases of intense bronchitis in drunkards, so that we may even speak of a "hemorrhagic bronchitis."

Dyspnoea is usually entirely absent in simple bronchitis, but marked shortness of breath may be noticed in extensive catarrh of the finer bronchi.

**Physical Examination.**—We may obtain direct evidence of the condition of the tracheal mucous membrane, with due practice, by the laryngoscope. We see a reddening of the membrane, and sometimes an abnormal abundance of secretion on it, if there is a tracheitis. Other methods of physical examination are at our service for judging of the changes in the bronchi.

Inspection of the thorax shows nothing abnormal in the milder forms of bronchitis. The respiration is somewhat accelerated and the expiration prolonged in severe bronchitis, especially if the finer bronchi are affected. Percussion in uncomplicated bronchitis shows nothing abnormal in the pulmonary resonance. Auscultation, too, shows nothing unusual in many cases of mild catarrh limited to the trachea and large bronchi, but in the cases where the smaller bronchi are the seat of the catarrh and there is a marked accumulation of secretion in them,

we hear, besides the vesicular respiration, the so-called rhonchi which almost wholly hide it. In dry bronchitis we speak of humming or buzzing sounds, sonorous rhonchi, or shrill, whistling sounds, sibilant rhonchi, according to their pitch. These sounds are probably due to stenosis, and are caused by the passage of the air through narrow portions of the bronchi. The narrowing occurs in part from the swelling of the mucous membrane, in part from the accumulation of secretion. The masses of secretion themselves, if they are set in vibration at the same time, may possibly take part in the production of the humming noises. If the amount of secretion collected in the bronchi is more abundant and of a more fluid consistency, it gives rise to "moist râles" on the passage of the air. These are distinguished as "medium" or "small moist râles," according as they occur in the larger or smaller bronchi.

Other symptoms of disease are often present besides those already mentioned as being directly due to the bronchitis. The general health is usually disturbed in a severe bronchial catarrh. The patient does not feel well, and has less appetite than usual. A moderate amount of fever is often present, especially toward evening. An increase of temperature above  $102^{\circ}$  or  $103^{\circ}$  ( $39^{\circ}$  C.) is rarely seen except in children. The patient sometimes complains of headache, which is increased by severe coughing.

The separate forms of bronchitis are distinguished chiefly by the degree of extension of the catarrh.

1. **The Milder Forms of Acute Bronchitis.**—In most cases of simple primary bronchitis, as well as in many milder attacks of secondary bronchitis, the catarrh is limited to the mucous membrane of the larger bronchi. Exposure to cold and other injurious influences are frequent causes of the primary form. The symptoms are moderate. The cough, however, may be quite troublesome. Often fever is absent or but slight. Upon auscultation, particularly over the lower lobes, but sometimes over the entire lungs, and usually with some symmetry of distribution, are heard numerous rather coarse wheezing or rattling sounds; but in many cases, as we have said, there may be nothing abnormal heard, so that the diagnosis will have to rest merely upon the subjective discomfort in the chest, the cough, and the expectoration. With proper care, simple primary bronchitis runs its course in a few days, or at the most in a few weeks, and ends in complete recovery. If the patient exposes himself recklessly, or the aetiological factors continue to be active, the disease may however prove to be very tedious, and finally develop into chronic bronchitis.

2. **The Severer Febrile Forms of Acute Bronchitis.**—Sometimes acute bronchitis assumes a severer form, whether because the influences which give rise to it are unusually violent, or because it is due to some special and as yet little known cause (perhaps infectious). In such cases the symptoms are more marked, the bronchial râles more abundant, the general condition of the patient worse. Not infrequently there is fever for several days, or even for one or two weeks, the type being irregularly remittent, but the temperature seldom exceeds  $102^{\circ}$  or  $103^{\circ}$  ( $39^{\circ}$  to  $39.5^{\circ}$  C.). The author has not infrequently noticed that there is more liability in the severer forms of acute bronchitis to have the disease mainly limited to one lobe, or at least to one lung, but the disease may be diffuse. This form of the disease also has a favorable prognosis except in feeble or elderly persons.

3. **Catarrh of the Finer Bronchi—Capillary Bronchitis.**—A simple primary bronchial catarrh rarely extends to the finer bronchi in adults. The secondary bronchitis, however, which develops in other severe diseases (*vide supra*), often extends into the ultimate divisions of the bronchi, and finally leads to the formation of nodules of lobular pneumonia—"catarrhal pneumonia" (*vide infra*). We recognize the implication of the finer bronchi by hearing the high, shrill, whist-

ling rhonchi [sibilant rhonchi], or the abundant small, moist râles. Respiratory symptoms may be quite marked in extensive catarrh of the finer bronchi. Respiration is evidently accelerated, and expiration is usually prolonged. There is often quite a severe cough. The expectoration is muco-purulent and usually not very abundant.

Capillary bronchitis in children is of great practical importance. Every bronchitis in young children has, as experience tells us, a tendency to attack the smaller bronchi. Extensive bronchitis is seen especially in weak children who are rachitic or predisposed to tuberculosis. Children have an especial predisposition to be attacked with bronchitis at the time of the first dentition, but it is also seen at an even earlier age.

The parents' attention is usually called to the disease by the appearance of a cough, which is excited especially by the child's crying. Small children never expectorate, for they swallow the secretion which is coughed up into the pharynx. The rapidity of respiration is very striking, it being increased to sixty or eighty, or even more, in a minute. The respiration is also labored, but it is usually superficial, and in severe cases irregular. There is generally a distinct respiratory play of the alae nasi. We often see a retraction of the lower lateral portions of the thorax on inspiration as a result of the imperfect entrance of air into the smaller bronchi. The expiration is frequently noisy and groaning in children. We hear extensive small, moist râles over the lungs. In severe cases the child becomes restless, anxious, perhaps markedly pale and cyanotic, and finally apathetic and stupid. In such cases, however, we have no longer to deal with simple bronchitis, but catarrhal pneumonia has already developed. The disease almost always runs its course with fever, the temperature rising to 104° (40° C.) and over. The pulse is increased to 120 or 140 or more per minute. The duration of the disease is seldom less than two or three weeks, and it may last much longer. Death may ensue, especially in ill-nourished children, partly as a result of general weakness, and also directly from the imperfect respiration. In such cases we find at the autopsy not only diffuse bronchitis, but also almost always lobular pneumonia. In many cases a gradual recovery finally takes place in spite of the most severe symptoms.

The secondary bronchitis in children complicating measles, whooping-cough, diphtheria, etc., has the same tendency to involve the finer bronchi and to lead to lobular pneumonia.

In conclusion, we must mention that acute bronchitis in old people also readily attacks the finer bronchi, and may be dangerous partly from the general exhaustion, partly from the occurrence of respiratory symptoms, as in lobular pneumonia.

**Diagnosis.**—The diagnosis of bronchitis presents no special difficulty. It is obtained directly by the discovery of rhonchi on auscultation. If these fail, we conclude that there is a mild catarrh of the larger bronchi from the presence of cough and expectoration, if no cause for the cough is to be found in an affection of the larynx. The question is more difficult, but it must always be considered, whether a given bronchitis is a common primary catarrh or secondary to some other affection. This question naturally can be decided only by a very careful examination of the body. We must always remember, furthermore, that severe pulmonary affections may be at first quite latent and show objectively merely the signs of simple bronchitis, while later pneumonia, a tubercular affection, or something similar, develops. A bronchitis which is unilateral, or in which the signs are to be found in circumscribed localities, must therefore be regarded as suspicious. It has long been known that bronchitis in the apices of the lungs, the "apex-catarrh," is often the first objective change to be met with in pulmonary phthisis. We can only conjecture, and not pronounce with certainty on objective evidence,

whether nodules of lobular pneumonia are present or not in diffuse bronchitis affecting the finer bronchi.

From what has been said, it is clear that we should be cautious in our prognosis regarding every severe bronchitis, especially in children and old people. The prognosis in the milder forms of bronchitis is of course always very favorable.

**Treatment.**—The prophylaxis of primary bronchial catarrh consists in the removal of all the injurious influences mentioned which, as experience shows, may give rise to a bronchitis. A careful hardening of the skin to the effects of a change in temperature is of service in persons, particularly children, who have a special tendency to bronchitis, as we have already said in regard to the prophylaxis of laryngitis. It is very important to remember, in this connection, that we can also be successful in our prophylactic measures against secondary bronchitis. Keeping the mouth and pharynx clean, urging deep inspirations, and aiding expectoration by the timely use of tepid baths and shower-baths, may often prevent a bronchitis or keep it within bounds, while it would surely develop if the patient were neglected.

Simple hygienic measures suffice in the treatment of mild cases of acute bronchitis. The patient should be kept warm, should remain in his room, or, if there be any fever, in bed. Diaphoretic remedies have long been praised as especially potent in the treatment of acute bronchial catarrh. The patient, therefore, should drink hot tea, pectoral tea\* (Brustthee), or elder tea, etc., or hot milk mixed with Seltzer, a remedy whose efficacy is frequently praised by the patient. Local treatment of the mucous membrane by inhalations is usually illusory, for only the smallest part of the inhaled fluid reaches the bronchi. We may, however, always prescribe inhalations of warm steam, or a one- or two-per-cent. solution of common salt, especially with a dry cough and a secretion which is hard to loosen.

Otherwise we must employ symptomatic treatment. A mustard plaster or a cold, wet compress about the chest does good service with severe subjective thoracic symptoms. In bad cases a few dry cups may be very useful in adults, but local abstractions of blood are never necessary in simple bronchitis. If there is troublesome irritation on coughing, so as to disturb the rest, we may prescribe small doses of morphine, five to ten grains of Dover's powder (grm. 0.3-0.5), fifteen to twenty drops of cherry-laurel water, codeine, etc. When expectoration is difficult, we may use the so-called expectorants—ipecac, chloride of ammonium, apomorphine, etc.

We have already repeatedly mentioned the use of tepid baths and shower-baths, indicated in severe diffuse bronchitis developing secondarily in the course of other acute diseases.

Tepid baths with shower-baths, two or three times a day, are also to be used as a most powerful remedy in severe cases of capillary bronchitis in children. The baths assist expectoration and guard against the possibility of the development of lobular pneumonia. Wet packs applied to the thorax or over the whole body are serviceable. Children are wrapped to the neck in a sheet which has been previously dipped in water at a temperature varying with the degree of the fever from 68° to 77° (16° to 20° R.) and well wrung out. It is well to leave the arms free. A dry woollen blanket may be wrapped around the moist sheet. This procedure must be repeated three or four times a day. As to other remedies, we use

\* A favorite German household remedy, consisting of an infusion of eight parts of althaea, three parts of licorice, one part oforris-root, four parts of colt's-foot, and two parts each of mullein and aniseed.—TRANS.

the same as in adults. With weak children our care must be to keep up the strength by furnishing the most nourishing food possible and giving small amounts of wine. An emetic is sometimes indicated in cases with an abundant accumulation of mucous in the bronchi, and is of good service. As experience has shown, we should use opiates for small children only with the greatest care. Senega and benzoin may be used as expectorants.

In the bronchitis of old people our chief aim should be to keep up and improve the patient's strength. We prescribe liquor ammonii anisatus, infusion of senega, etc., to aid expectoration, which is usually difficult, since the cough is feeble. Tepid baths may be of advantage, but they must be used with care.

## CHAPTER II.

### CHRONIC BRONCHITIS.

(*Chronic Bronchial Catarrh.*)

**Ætiology.**—Chronic bronchial catarrh may develop gradually from external causes, or in rare cases it may follow an acute bronchitis. The same noxious influences which excite an acute bronchitis may, by the frequent repetition of their action, result in a chronic bronchitis.

In a large number of cases severe chronic bronchial catarrh is not an independent disease, but occurs as a complication or a result of other diseased conditions. The combination of chronic bronchitis with emphysema of the lungs (*vide infra*) is the most common. A large number of cases also are the result of some form of heart disease, like valvular disease or myocarditis, or of disease of the vessels, leading to stasis in the pulmonary circulation, and finally to a chronic catarrh of the bronchi. Chronic bronchial catarrh in renal diseases also depends, in part at least, upon circulatory disturbances. Finally, we find a more or less extensive chronic catarrh of the bronchi in other chronic affections of the lungs and pleura, as in tuberculosis or pleurisy.

Chronic bronchitis is seen especially in adults and old people, and more frequently in men than in women.

**Pathological Anatomy.**—Chronic bronchitis is characterized anatomically by a marked venous hyperæmia of the bronchial mucous membrane. The whole tissue itself is often thickened, and the surface of the membrane is swollen. In old cases, however, we finally meet with an atrophy of all the layers of the mucous membrane. One of the most frequent results of a chronic bronchitis is a cylindrical dilatation of the middle and lesser bronchi—bronchiectasis. This arises gradually from the loss of elasticity of the diseased bronchial walls, increasing their tendency to give way, as well as from the pressure of the stagnating secretions.

**Symptoms and Course of the Disease.**—The symptoms which are due to chronic bronchitis are disturbances of respiration, cough, and expectoration. To these should be added the results of a physical examination.

The cough is of very different severity in different cases. Usually it is worse early in the morning, in the evening, and at night, than in the daytime. The amount of expectoration is also subject to great variations. In many cases there is a dry cough (*catarrhe sec.*, *vide infra*), in which only small amounts of tough, viscid sputum are expectorated. In other cases the expectoration is more abundant and muco-purulent, and sometimes excessive and quite thin. Microscopically, it has no special characteristic appearances, but it contains only the usual

elements of sputum—pus-corpuscles mixed with pavement epithelium, often many bacteria, sometimes needles of fat acids, and rarely a few pointed octahedral crystals, the so-called asthma crystals (*vide infra*). Small amounts of blood may be seen in severe chronic bronchitis, but they do not have any bad significance.

Dyspnoea of moderate degree may also be present in uncomplicated and extensive bronchitis. In the cases in which it is severe, however, it is usually due to other conditions affecting the heart or lungs.

*Physical Examination.*—The percussion in bronchitis shows no special change. At most the resonance may be somewhat tympanitic from the relaxation of the lung-tissue, especially in the lower and posterior portions of the lungs, or, with an abundant retention of secretion in the bronchi, it may be a little diminished. Auscultation may give either rhonchi, whistling, hissing, humming, etc., or moist râles, according to the extent of the catarrh and the amount and consistency of the secretion. The sounds are usually to be heard over the whole lung, or especially over the lower lobes, because here the catarrh is usually most marked, and retention of secretion is most apt to occur. The respiratory murmur in some places may be quite obscured by the râles. Otherwise it is vesicular, sometimes exaggerated, sometimes rough and indefinite. Expiration is usually prolonged. The respiratory murmur may be much diminished, or even entirely suppressed in places where the bronchi are stopped by secretion, which happens most frequently in the lower lobes.

Except in mild cases, we usually distinguish several different forms of chronic bronchial catarrh, which may run into one another.

1. The dry chronic catarrh (*catarrhe sec* of Laennec) is the form in which the mucous membrane has only a very slight secretion. The cough is usually very troublesome and labored, but the patient raises merely a little tough sputum, or none at all. On auscultation we hear sibilant rhonchi, but no moist râles. This form of catarrh is usually associated with pulmonary emphysema, and asthmatic attacks are also frequent. The disease is stubborn, and usually lasts for years.

2. The so-called bronchial bleorrhœa is that form of chronic bronchitis in which we find a very copious secretion from the mucous membrane. The cough is therefore associated with a very abundant and quite thin expectoration, the amount of which in the twenty-four hours may exceed a pint (half a litre). The expectoration runs together in the sputa-cup and usually separates on standing, the more purulent portion sinking to the bottom, and the sero-mucous portion, which is usually frothy on the surface, remaining at the top. Numerous moist râles are heard in the lungs, especially in the lower portions. These diminish if large amounts of sputum are coughed up. Anatomically, the bronchi are almost always found dilated in this form of chronic bronchitis.

3. The so-called serous bronchorrhœa ("*catarrhe piteux*" of Laennec) is quite rare but very interesting. It is characterized by the expectoration of a very large amount of frothy, purely serous, thin sputum. The cough usually comes on in very violent paroxysms which last from half an hour to an hour or more. The respiratory symptoms are quite severe, especially during these attacks, and have given rise to the old and useful term "*asthma humidum*." The expectoration collected in twenty-four hours may amount to one or two quarts (litres). Examination of the lungs usually gives very abundant and extensive moist râles. The resonance on percussion is normal or a little diminished, from the accumulation of secretion.

The special cause of this peculiar disease is quite obscure. It is either an independent, very chronic trouble, which may last for years with a varying course, or it may occur secondarily in other affections, especially in chronic contraction of the kidney. We once saw a very severe case of the independent and apparently

quite uncomplicated form in a young woman who had high fever at times, and who became much broken down physically.

**Course of the Disease.**—The course of most chronic bronchial catarrhs is very protracted. The disease usually has frequent remissions and fresh exacerbations. The patient is tolerably well in the pleasanter time of the year if he takes good care of himself, but in autumn and winter, or after exposure to various noxious influences, the catarrh grows worse and the patient's symptoms increase. If the disease has lasted for years, we usually find symptoms in the lungs, like emphysema or chronic tuberculosis, or in the heart, like secondary dilatation and hypertrophy of the right ventricle, which symptoms gradually become more severe. The details of these conditions are to be found in the appropriate sections.

**Diagnosis.**—The diagnosis of chronic bronchitis is not difficult in itself, and may easily be made by considering the patient's symptoms and by judging of the result of the physical examination. We must always consider, however, whether the bronchitis is not a result or a complication of some other chronic disease. Therefore in every case of chronic bronchitis the heart and the urine must be carefully examined, as well as the lungs.

**Prognosis.**—Chronic bronchitis is in most cases a very stubborn affection, which frequently shows improvement, but from which complete recovery is rare. The prognosis also depends greatly upon the patient's circumstances, and upon the possibility of his taking care of himself and avoiding all harmful exposure. In secondary bronchitis the question whether the bronchitis is capable of material improvement or not of course depends mainly upon the prognosis of the primary disease.

The danger in primary chronic bronchitis comes from the final development of its sequelae, especially from the gradual appearance of pulmonary emphysema, dilatation of the heart, etc.

**Treatment.**—The only hope of success in severe cases in any method of treating chronic bronchitis is in removing the patient completely, at least for a time, from the action of injurious influences. The favorable result of the baths and health resorts that are employed depends largely upon this, that patients enjoy in them complete bodily rest, and are far better protected from dust and the changes in the weather than at home. We must make the patient comprehend the necessity of this condition as the basis of any treatment. If he can not go to a suitable climate during the cold season, he must keep his room in all unpleasant weather, but at other times he may be permitted to stay in the open air. Furthermore, the patient must be warned to avoid as completely as possible those harmful influences which his calling and manner of life entail, and among which especially is the bad air in our inns and restaurants. Food should be easily digestible, and, in people inclined to corpulence, sparingly taken. Alcohol is to be permitted only in a moderate degree. We combat the tendency to constipation, which is often present, by dietetic remedies, by taking fruit, especially grapes, prunes, etc., honey, Graham bread, or by mild laxatives, like the bitter waters, Friedrichshall, Ofner, etc.

If the circumstances of the patient permit and his condition requires it, we should send him south in the autumn in order to avoid the evils of a northern winter. The rule is to send patients with a bronchial catarrh when there is much secretion to health-resorts with a dry climate—for example, to the western Riviera, San Remo, Bordighera, Mentone, Cannes, etc. The somewhat dry yet cooler climate of Meran, Gries, or Arco is suitable for patients with a stronger constitution. Patients with dry bronchitis usually find themselves at their best in a warm but not too dry climate. If we wish to be sure of avoiding the winter's cold, we must choose Sicily, Egypt, or Madeira for a residence. Of the more

northern winter resorts we may mention here places on the eastern Riviera, Nervii, Spezzia, etc., except Venice, Pisa, or Rome.

We must recommend especially, in bronchitis, a suitable summer residence outside of large and dusty cities. Any private country residence in a well-wooded and protected place is of advantage. If we wish to send patients to a bath, Marienbad, Kissingen, or Homburg are proper places for corpulent people who also suffer from digestive disturbances, while we may send weaker patients to Ems, Soden, Badenweiler, Ischl, or Reichenhall. Milk cures, whey cures, and grape cures are also prescribed in many cases of chronic bronchitis, the milk cure in particular for weak and anæmic individuals. A summer residence on the sea, best on the Baltic, is very serviceable for many patients with bronchitis.

The inhalation treatment is much employed in chronic bronchitis, but we should not cherish too high hopes about its use. The best inhalations in dry catarrhs are simple steam, a two-per-cent. solution of common salt or bicarbonate of sodium, Ems water, etc. In cases with marked secretion, inhalations of oil of turpentine are most to be praised. The simplest way is to pour a teaspoonful of oil of turpentine into hot water and inhale the vapor as it arises. The so-called turpentine-pipe, however, is more convenient and more efficacious. This consists of a flask, which is filled to the height of several inches with water and then with a layer of oil of turpentine or of *oleum pini pumilionis* (P. G.), some two centimetres thick. Two glass tubes, open at both ends, are passed through the cork. One, straight, tube extends down into the layer of water; the lower end of the other is free in the upper part of the flask. The outer portion of this last tube is long enough to be bent at an angle and forms the mouth-piece of the pipe which the patient sucks. He thus breathes the air which is filled with turpentine vapor. We have treated many patients in this way, who, for a number of hours a day, "smoked" their turpentine-pipes.

In treating chronic bronchitis the pneumatic method\* was considerably employed for a time; that is, the patient was made to breathe artificially compressed air, or to expire into air of a less than atmospheric tension, by means of a movable pneumatic apparatus, as proposed by Waldenburg and others. Of late, however, this method of treatment has received less favor, inasmuch as actual results have fallen decidedly short of the benefit promised. In Ems, Reichenhall, and other places special pneumatic cabinets have been arranged, filled with compressed air, in which patients remain for varying lengths of time.

The different alkaline mineral waters—Seltzer, Ems, Victoria, etc.—are next to be mentioned among internal remedies, which may also be used efficaciously at home. The numerous expectorants, like ipecac and apomorphine, are especially valuable in dry bronchitis. In bronchial blennorrhœa we know empirically that the internal use of balsams causes a distinct diminution of the secretion. Oil of turpentine is the most active, and may be given internally in gelatine capsules, two or three capsules a day, or mixed with milk, in doses of ten or fifteen drops two or three times a day. Lépine, G. Sée, and other French physicians recommend terpine as still more effectual. This is a derivative of turpentine, and is best employed in pills containing one and a half grains (0.1), of which two or even more are to be taken three times a day. It may also be given in solution

\* Details of the pneumatic treatment may be found in the following works: R. v. Vivenot, Jr., "Zur Kenntniss der physiologischen Wirkungen und der therapeutischen Anwendung der verdichteten Luft," Erlangen, 1868. Waldenburg, "Die pneumatische Behandlung der Respirations- und Circulationskrankheiten," Berlin, 1880. Knauth, "Handbuch der pneumatischen Therapie," Leipzig, Wigand, 1876. Schnitzler, "Die pneumatische Behandlung d. Lungen- u. Herzkrankheiten," Wien, 1877 (40 Seiten). Oertel, "Handbuch d. respiratorischen Therapie" (v. Ziemssen's "Allg. Therapie," ii, 4), Leipzig, Vogel, 1881.

as follows : Terpine, 2½ drachms (grm. 10); alcohol, q. s. ad sol. faciundam; aq. dest., 6 ounces, 6 drachms (200 grm). Misce. Sig: Two or three tablespoonfuls daily. Balsam of copaiba and balsam of Peru are also used internally. We should be very sparing of narcotics at first, but in severe cases we can not wholly dispense with them.

[The iodide of potassium in doses of five to ten grains thrice daily is sometimes distinctly curative. An out-door life, free diet, moderate alcoholic stimulus, tonics, and woolen clothing do much to promote recovery.]

Local applications to the chest in the form of embrocations, mustard plasters, dry cups, or cold wet compresses are to be used, especially with severe dyspnoea, or with pain and a feeling of oppression in the chest. Regular cold sponging of the chest serves to harden and strengthen the patient.

Warm baths are very well borne by many patients with chronic bronchitis. Sometimes, too, vapor baths, if taken with caution, may be of service, especially in strong and corpulent patients.

In all secondary chronic catarrhs our chief attention, beyond the symptomatic treatment of the bronchitis, must be directed to the treatment of the underlying disease. If we succeed in once more regulating the heart's action where there is uncompensated heart disease, or in establishing diuresis where there is renal disease, we may also in that way cause improvement in the existing bronchial catarrh.

### CHAPTER III.

#### FŒTID BRONCHITIS.

(*Putrid Bronchitis.*)

**Ætiology.**—By putrid or fœtid bronchitis we mean that form of bronchitis in which the secretion of the mucous membrane undergoes a putrid decomposition, and in which, consequently, the expectoration takes on a peculiar and extremely foul odor. The cause of fœtid bronchitis is usually the entrance of the bacteria of putrefaction into the bronchi by means of the inspired air. Only in rare cases does it arise from a pulmonary gangrene of embolic origin (*vide infra*).

The opportunity for the agents of putrefaction to enter the bronchi with the inspired air is of course often given, but a fœtid bronchitis naturally is excited only when they can remain there and increase. Their retention and their further development is chiefly favored, as we know, by diseased conditions which already exist in the bronchi. A great number of cases of fœtid bronchial catarrh therefore develop secondarily upon other pulmonary affections of longer standing. Thus the expectoration may quite suddenly change and take on a fœtid character in the course of a chronic or rarely of an acute bronchitis or of phthisis. Bronchiectasis (*vide infra*) greatly favors the development of this putrid change, for in it the retention and stagnation of large amounts of secretion furnish the aid and occasion for it. If a putrid decomposition of the secretion begins in one part of the bronchial system, the further extension of the process follows from direct infection.

In rare cases putrid bronchitis also develops in lungs which were previously apparently sound—primary fœtid bronchitis.

**Symptoms and Course; Anatomical Changes.**—If a fœtid bronchitis arises in the course of some other chronic pulmonary disease, its appearance may be marked by a sudden impairment of the general condition, by high fever, often associated with numerous chills, and by an increase of the thoracic symptoms, like pain and

cough. The change in the expectoration, the peculiarity of which was first accurately described by Traube, is characteristic. There is a repulsive, sweetish, putrid smell. The expectoration is usually quite abundant; the consistency is rather thin. On standing, the sputum shows a very marked division into three layers. The upper layer consists of a very frothy, muco-purulent stratum, consisting in part of individual masses, from which a number of coarser or finer fibers float down into the middle layer. This middle layer consists of a dirty-green muco-serous fluid. At the bottom of the vessel is found the third layer, which is often the thickest, and is composed entirely of pus. It consists of pus-corpuscles which have sunk to the bottom, and is of a rather thin, greasy consistency. With the naked eye we generally recognize a number of little whitish-gray plugs and particles in it. These so-called "Dittrich's plugs," which are easily crushed under

a cover-glass, are quite characteristic. Microscopically, they consist of decomposed pus-corpuscles, detritus, and bacteria, and usually contain very many needles of fat acids arranged in bundles (see Fig. 21).

FIG. 21.—Crystals of fat acids.

We often find also in the sputum large masses of fungi, especially great bunches of twisted lepto-thrix fibers, which, by an unpracticed eye, may readily be mistaken for elastic fibers. The latter are, of course, never found in the expectoration of a simple foetid bronchitis, but only in the deep-seated, destructive processes in the lung, like gangrene. On chemical examination of the sputum,

the ordinary products of putrefaction may be found—volatile fat acids, especially butyric and valerianic acids, also sulphuretted hydrogen, leucine, tyrosine, etc.

The breath of the patient, as well as the sputum, is very often foul-smelling, and so offensive that he becomes a burden to his associates.

The signs which foetid bronchitis gives on physical examination are those of an ordinary bronchitis. In a great number of cases we also find signs of consolidation and contraction of the lung, of pleurisy, etc., which do not belong to foetid bronchitis as such, but are due to complications or sequelæ.

The most frequent of these sequelæ is the development of a "reactive" lobular inflammation, a pure pneumonia, which follows a catarrh which has attacked the finer bronchi. These pneumonias frequently run into gangrene, so that we very often find a number of larger or smaller nodules of pure gangrene besides the extensive foetid bronchitis in the lungs. In many of these cases the foetid bronchitis is certainly the primary process, and the development of the nodules of gangrene is secondary; yet we shall see later that the reverse may also be true. Foetid bronchitis and gangrene of the lungs run into each other so often, both clinically and anatomically, that there is no sharp line to be drawn between them. If the nodules are superficial, and reach the pleura, the infection attacks this, and we have a purulent or even an ichorous pleurisy.

The smaller and medium-sized bronchi are almost always found in a condition of cylindrical dilatation in old foetid bronchitis. Their mucous membrane is intensely inflamed, and often ulcerated superficially. On its surface we see in the cadaver the greasy purulent masses and the plugs which we find in the expectoration during life.

Whatever may be the case with the general course of foetid bronchitis, its beginning is often quite sudden and acute, both in the primary and in the secondary forms, as we have said. The patient is attacked with fever, which may often be quite high, and with a stitch in the side, and cough, and expectoration. Later,

the characteristic peculiarities described above appear. The further course of the disease is almost always chronic, lasting for years, but subject to many variations. Very often manifest improvement, and even apparent recovery, takes place, until suddenly there is a new attack of fever and thoracic symptoms. The general condition and nourishment of the patient may be quite good for a long time, except during the periods of marked exacerbation of the disease. Patients with chronic foetid bronchitis often appear somewhat bloated, but also pale and slightly cyanotic. Peculiar clubbed thickenings of the terminal phalanges of the fingers gradually develop, as in many cases of bronchiectasis. Slight œdema of the lower extremities is also sometimes present.

Symptoms referable to other organs may be wholly absent. We see most frequently disturbances of the stomach, loss of appetite, and nausea, which probably comes from swallowing the foetid sputum. Patients also complain of occasional rheumatic pains in the muscles and joints, which may perhaps be due to an absorption of septic matter. In conclusion it must be mentioned that in fortunately rare cases of foetid pulmonary disease pyogenic germs reach the brain by metastasis, and here give rise to purulent meningitis or cerebral abscess.

The danger of the disease, apart from the exceptional occurrence just mentioned, lies in the possible extension of the process to the lungs and the development of pulmonary gangrene and its sequelæ. We hardly ever find a simple foetid bronchitis in the cadaver, but we almost always see other processes besides, which have been mentioned above—reactive pneumonia, pulmonary gangrene, etc. These processes develop very readily, and make rapid progress in old, decrepit persons, who live under bad external conditions, in whom putrid processes in the lungs are frequent.

The **diagnosis** of foetid bronchitis is not difficult in itself, for the diagnosis of a putrid process in the lung may be made from the stinking sputum alone. It may be difficult to decide whether we have to do merely with a foetid bronchitis, or with a pulmonary gangrene also. Decisive indications of gangrene are derived from physical examination—dullness, bronchial respiration, and large, moist râles—and also the discovery of elastic fibers and fragments of parenchyma in the expectoration.

The **prognosis** must be made with care in every case of foetid bronchitis. If the external circumstances of the patient are favorable, he may remain in tolerable health for years. We must always be prepared for the appearance of new exacerbations of the disease and of affections of the lung itself.

**Treatment.**—The chief aim of treatment must be to bring the putrid processes in the bronchi to a stand-still by the death of the agents of putrefaction. The difficulty of fulfilling this task lies in the impossibility of getting the disinfecting material to act on the bronchial mucous membrane in the necessary amount and concentration. Nevertheless, we can, without doubt, at least relieve a foetid bronchitis and keep it in check by the judicious use of inhalations. Inhalations of a two-per-cent. solution of carbolic acid are most useful, given for five or ten minutes several times a day. These, however, are sometimes not well borne if long continued, and they may excite mild symptoms of carbolic poisoning—like headache, malaise, and dark carbolic urine. We have often used with good results the "carbolic mask" recommended by Curschmann, a kind of respirator fastened in front of the nose and mouth, containing cotton in a special receptacle impregnated with carbolic acid, equal parts of carbolic acid and alcohol, or other remedies like turpentine or creasote. Many patients can wear these masks, with occasional interruptions, for many hours a day. Turpentine is most used next to carbolic acid. Turpentine can be used by inhalation and also internally. Likewise terpine and myrtol are often of decided benefit. We have very recently, in the

clinique at Erlangen, had good results from inhalations of *oleum pini pumilionis* (employed as described on p. 154 for the inhalation of turpentine). Both inhalations and the internal exhibition of turpentine are of distinct value. We may also try acetate of lead internally, one or two grains (grm. 0.05-0.10) in powder every two hours.

In other respects all the general hygienic and symptomatic methods of treatment recommended for common chronic bronchitis are also useful in foetid bronchitis. The sputum should be disinfected by putting strong carbolic acid, etc., into the sputa-cup to lessen the bad odor. It is a very good plan to keep the carbolic spray at work in the patient's room as often and as long as possible, or the air may be impregnated with *oleum pini pumilionis*.

#### CHAPTER IV.

##### CROUPOUS BRONCHITIS.

(*Fibrinous or Pseudo-membranous Bronchitis*.)

CROUPOUS bronchitis is a peculiar form of disease of the bronchial mucous membrane, of very rare occurrence, in which there is a formation of extensive fibrinous patches in the bronchi. Only that form of croupous bronchitis which occurs primarily in the bronchi is to be considered here, and not the secondary form, which on the one side is associated with diphtheria in the pharynx and larynx, and on the other with croupous pneumonia.

The **ætiology** of the disease is as yet wholly unknown. From analogy with other well-known croupous inflammations of mucous membranes, we must look here for some noxious influence which destroys the epithelium, but up to this time we are entirely ignorant of its character. Individuals in youth and middle age, somewhere between ten and thirty years old, are the chief victims. Men are attacked somewhat more frequently than women. The disease comes on either in persons who were previously healthy—the essential croupous bronchitis—or in those who have already suffered from some other disease, especially some chronic pulmonary affection—the symptomatic, secondary croupous bronchitis. It is not certain whether the last-named cases can have the same ætiological relation as the cases of pure primary fibrinous bronchitis. Fibrinous bronchitis has been observed in the course of typhoid fever.

**Symptoms and Course.**—Primary fibrinous bronchitis occurs in two forms, acute and chronic. The acute form begins quite suddenly, with fever, cough, pain in the chest, and severe dyspnoea which speedily develops. The fibrinous coagula, which alone render the diagnosis possible, appear in the expectoration either at once, or after the existence for some days of what is apparently simple catarrhal bronchitis.

These coagula form complete casts of the bronchi, and are more or less branching. They are of a whitish color and of quite a dense, elastic consistency. The main stem may be a centimetre thick, and from it the further ramifications branch, dividing dichotomously. The largest casts are ten or fifteen centimetres long. On section, we usually find a free lumen within, and generally recognize a definite laminated structure in the membrane. In many places they are enlarged and swollen. Microscopically, we find white blood-corpuscles in and upon the hyaline ground-substance of the casts, and also red blood-corpuscles, sometimes epithelial cells, and quite often the peculiar pointed octahedral crystals which are also found in the expectoration in bronchial asthma (*vide infra*). The so-called "spirals"

(*vide infra*) have also been found in the expectoration of fibrinous bronchitis. Chemically the casts consist of coagulated albumen. Their solubility in alkalies, especially in lime-water, is of therapeutic importance.

On coughing, the patient usually raises a simple mucous or muco-purulent expectoration beside the casts, and in this sputum the casts are imbedded. They are often first discovered by pouring the whole amount of sputum into water, when they unfold and spread out. The expectoration also contains not infrequently a slight admixture of blood.

The subjective symptoms of the patient may be very violent. The dyspnoea sometimes attains a high and alarming degree. It ceases when a large cast is expectorated after a severe paroxysm of coughing. Such attacks may recur every day or two. In other cases, however, the subjective symptoms are comparatively slight.

Physical examination of the lungs gives little that is characteristic. In uncomplicated cases percussion gives nothing abnormal, or at most the signs of an acute emphysema. Auscultation gives the ordinary signs of bronchitis, not characteristic in themselves, such as rhonchi, or moist râles. If a large bronchus is plugged, the respiratory excursions and the respiratory murmur are almost entirely absent in the corresponding portion of the lung, but after the expectoration of a cast the murmur once more becomes audible.

The duration of acute cases is sometimes only a few days, at most a few weeks. In favorable cases the fever, which at times is quite high, soon disappears, the respiratory symptoms grow milder, the expectoration of the casts ceases, and there is a complete and permanent recovery. In severe cases, however, death often ensues with all the symptoms of suffocation. The acute form sometimes becomes chronic, but this is rare.

The chronic form of fibrinous bronchitis may last for years. Usually the condition grows worse periodically, at varying intervals of time, and at each exacerbation casts are expectorated, while in the interval there is apparently merely a simple bronchial catarrh. Some observations are also recorded in medical literature of people who have expectorated these casts at intervals for years without any special disturbance of their health or their nutrition. In some cases other chronic pulmonary affections, like tuberculosis, finally develop.

The pathological anatomy of fibrinous bronchitis is not yet satisfactorily known on account of the rarity of the affection. The changes in the lungs found at the autopsy of fatal cases have usually been complications, like pneumonia, pleurisy, or tuberculosis, which stood in no direct relation to the fibrinous bronchitis. A loss of epithelium has been discovered in some cases in the parts of the bronchial mucous membrane that were attacked.

**Prognosis.**—In all acute cases the prognosis should be guarded, for we know that about one fourth of the cases terminate fatally. The chronic cases, as has been said, are usually very protracted and are subject to frequent recurrences, but they differ from the acute cases in being much less dangerous.

**Treatment.**—We make special use for inhalations of those remedies which, as we have said, are able to dissolve the casts. We usually employ a two-to-five-per-cent. solution of carbonate or bicarbonate of sodium, and above all lime-water, either pure or diluted with an equal volume of water. The internal administration of iodide of potassium, in doses of twenty to forty-five grains (grm. 1.5-3.0) a day, proves of advantage in many cases. Energetic inunction with mercurial ointment is sometimes of service. Expectoration of the casts may be aided in many cases by such expectorants as senega and benzoic acid, or by the timely use of emetics. We do not know any remedies which are able to prevent a return of the attacks in the chronic form. The treatment except at the time of the attacks, is the same as in ordinary chronic bronchial catarrh.

## CHAPTER V.

## WHOOPING-COUGH.

( *Pertussis*. *Tussis convulsiva*.)

**Ætiology.**—By the name “whooping-cough” we mean a specific disease of the mucous membrane of the air-passages, which is chiefly seen in children, and is characterized by a peculiar violent and paroxysmal cough. Sporadic cases are of almost constant occurrence in large cities, but the disease often appears in epidemic outbreaks. Epidemics of whooping-cough follow epidemics of measles with remarkable frequency.

Whooping-cough is without doubt contagious, and therefore often attacks one child after another in the same family. Kindergartens, orphan asylums, and nurseries aid very much in extending the disease. The contagious element seems to be connected with the air expired by the patient, particularly with the secretion from the mucous membrane expectorated after coughing. Children are most subject to an attack up to the age of six years; from that age the disposition to the disease decreases rapidly with increasing years. Whooping-cough is seen, indeed, in adults, but it is quite rare, and almost always comparatively mild and rudimentary.

The epidemic onset, the contagiousness, and the whole course of the disease favor the theory of its infectious nature. The presence of the organisms which are supposed to be the poison of the disease has not yet been certainly demonstrated, although many have claimed to discover characteristic organisms in the sputa of patients. These statements, however, all conflict, and lack well-attested and methodical proof. If a patient has once had the disease, he is almost invariably secure against a new attack.

**Symptoms and Course of the Disease.**—Whooping-cough begins with the symptoms of a catarrh of the trachea and bronchi, which develops more or less rapidly, and which at first often shows nothing characteristic. We can at this period make a tolerably probable diagnosis only at a time when an epidemic is prevailing, or in case the child's associates have already been attacked with the disease. The cough is often quite severe at the beginning, but it does not yet come on in distinct paroxysms. Examination of the chest shows nothing peculiar except a few rhonchi. There is often a coryza, with frequent sneezing, and there is sometimes a mild conjunctivitis. The child is restless and feverish, especially toward night. The temperature may repeatedly reach 103° or 104° (39°–40° C.) in this initial fever. The duration of this first so-called catarrhal stage varies, but it usually lasts a week or ten days.

The catarrhal stage gradually passes into the second, convulsive stage, without any sharp boundary. The cough becomes more violent, and comes on in the separate paroxysms of whooping-cough which are characteristic of the disease. We do not know the particular reason why the cough has this paroxysmal character, but a nervous factor probably plays the chief part in it.

The peculiarity of the attack consists in the violent, paroxysmal fits of coughing, which are from time to time interrupted by deep, long-drawn, loud, and shrill inspirations, due to the occurrence of a spasmodic contraction of the glottis. Exceptionally there are cases without this loud whistling inspiration. The child becomes markedly cyanotic during the attack, the veins in the neck swell, and tears come into the eyes. Hæmorrhage into the conjunctiva, nose-bleed, and in some cases hæmorrhages into other organs, like the ear, the skin, and the brain,\*

\* In one instance we observed the very rare occurrence of a hemiplegia during a paroxysm of whooping-cough.

often come on as a result of this stasis. Vomiting very often occurs either during a paroxysm or at its close. Involuntary evacuations of urine and feces may also follow from the violent contraction of the abdominal muscles. Exceptionally we observe still more severe symptoms with a paroxysm: a complete spasmodic cessation of respiration with imminent danger of suffocation, or sometimes general convulsions.

The paroxysms vary with the severity of the disease, frequently appearing ten or fifteen times in twenty-four hours; sometimes with greater frequency—fifty times or more. They also occur at night as often or even oftener than in the daytime. They come on either spontaneously or from some special predisposing cause. We may, for example, excite a paroxysm artificially by pressing on the larynx or by making the child cry. If there are several children with whooping-cough in the same room and a paroxysm attacks one of them, the others, as a rule, soon begin to cough too. Some prodromal symptoms often precede the peculiar paroxysm, such as general uneasiness, rapid respiration, or vomiting. At the end of a paroxysm many children remain very feeble and exhausted, but others recover very rapidly, and are playing again quite briskly a few minutes after.

In general the child feels quite well in the interval between the paroxysms, but the effects of the violent attacks of coughing may of course often be seen. Besides the occasional hemorrhages into the conjunctiva, we find the eyelids somewhat swollen, their veins dilated and blue, and showing through the skin. A small ulcer is quite frequently formed on the frænum of the tongue, the origin of which is to be referred to mechanical causes. The tongue is violently protruded in the severe paroxysms of coughing, and the frænum is thus pulled or torn, or injured by the sharp lower incisors.

Physical examination of the lungs shows nothing abnormal in uncomplicated cases except a few moist râles or rhonchi. Sometimes the rhonchi are wanting, or are present in small numbers only a short time before a paroxysm, but in other cases an intense diffuse bronchitis is developed, which often leads to the development of a lobular pneumonia (*vide infra*). Sometimes, but not always, there is an acute catarrhal inflammation of the bronchi, and especially of the posterior wall of the larynx.

The fever, which is usually present in the first or catarrhal stage, is absent in the convulsive stage. The child is free from fever for the most part. We often find a slight rise of temperature up to 100° or 101° (38°–38.5° C.), but only toward night. Higher and more persistent fever points to the development of complications, especially on the part of the lungs.

The convulsive stage seldom lasts less than three or four weeks, and often much longer, up to three or four months. The paroxysms gradually become less frequent and less violent (*stadium decrementi*), until they finally disappear entirely; but relapses and fresh exacerbations also occur in this stage. Finally, however, the disease, in uncomplicated cases, goes on to a permanent and complete recovery.

**Complications and Sequelæ.**—The severe results which sometimes follow whooping-cough are probably partly due to the direct action of the specific causes of the disease, and partly to complications of a secondary nature whose origin is merely favored by the whooping-cough. The most important are complications in the lungs. A lobular, catarrhal pneumonia often develops after a severe bronchitis which involves the finer bronchi. In such cases the respiration becomes hurried and superficial, the fever higher, and the general condition bad even in the times between the paroxysms. On examination of the lungs, we hear numerous moist râles, especially over the lower lobes, and we can sometimes

make out dullness on one or both sides if there is extensive pneumonic infiltration. Such cases are always very protracted, and many children succumb, partly from the disturbance of respiration and partly from general weakness and inanition.

Complications in other organs are much rarer. Among the most frequent are attacks of diarrhœa which exhaust the child's nutrition. Many observers have also mentioned the quite frequent occurrence of a croupous or diphtheritic inflammation in the pharynx and larynx in the course of whooping-cough. Finally, a case under our own observation may here be mentioned, in which death occurred with severe nervous symptoms, convulsions, and coma. At the autopsy very numerous capillary hæmorrhages were found in the brain.

Pulmonary emphysema is the first thing to be mentioned among the sequelæ of whooping-cough. From the marked pressure which the severe and frequent outbursts of coughing exert from within upon the alveoli of the lungs, they gradually become dilated. An acute lobular emphysema ("acute pulmonary inflation") is set up which sometimes passes into a typical chronic pulmonary emphysema (*vide infra*). Chronic bronchial catarrh may also remain for a long time after an attack of whooping-cough.

A third important sequel of whooping-cough is pulmonary tuberculosis. The bronchitis and lobular pneumonia which occur during a whooping-cough sometimes do not improve, especially in weak children with a tubercular tendency. The fever continues high, the child grows thin, and constantly becomes more and more miserable. At the autopsy we find cheesy nodules in the lungs, cheesy bronchial glands, and at times tuberculosis of other organs. These cases signify that when a tubercular infection is present, but is still latent, the whooping-cough acts as an exciting cause for the outbreak of the disease, or that a greater receptivity to infection with tubercular poison is created by the whooping-cough. Möbius has lately reported the occurrence in a few cases of paralysis as a sequel of whooping-cough. This usually begins in the lower and extends to the upper extremities, and is apparently due to neuritis.

The **diagnosis** of whooping-cough can not be made with certainty, as we have said, until the second or convulsive stage. It is easy then, however, since the characteristic attacks occur in no other affection of the lungs in like manner and with like frequency and duration. If we have no opportunity to observe the attack itself, and have to depend upon the description of the friends, the diagnosis is sometimes more uncertain. In such cases, however, certain signs are often present: the child has a bloated aspect, or we may find slight hæmorrhages into the conjunctiva, or ulcers on the frænum of the tongue, which make the diagnosis highly probable. Under some circumstances we may also make the attempt to bring on the paroxysm artificially (*vide supra*).

The **prognosis** is favorable with the majority of children if they are previously strong and healthy. Very young children are in more danger than older ones. There is danger if secondary pneumonia develops, and if the general nutrition and strength of the child suffer. As soon as the diagnosis is certain we must call the attention of the parents to the probable long duration of the disease. Regard must also be paid to the possibility of the development of sequelæ, especially in weak children suspected of tuberculosis.

**Treatment.**—Since the disease is protracted and is not devoid of danger, it is our duty, when an epidemic of whooping-cough prevails, to guard children from it as far as possible. If one child in a family is taken ill, the other children must be rigorously kept away from him. If circumstances permit, we should prefer to send them away to another place free from whooping-cough.

With regard to the treatment of the disease, we must first endeavor to fulfill general dietetic and hygienic indications. The child should breathe good, pure

air, and for this reason it is often advisable to transfer the patient to a larger room, with as much air and sunlight as possible. The atmosphere should not be too dry, and it is advisable to employ a spray of carbolized water occasionally, or to hang up sheets moistened with the same in the room. In good weather the child should be out of doors a large part of the time, provided fever has ceased. City children are to be sent, if possible, into the country. The food should be good and nourishing, but dry and crumbly articles should be avoided, being apt to excite cough. Warm or lukewarm baths frequently prove very beneficial, particularly when there is considerable bronchitis, as they lessen the danger of a lobular pneumonia.

The medicinal treatment of whooping-cough has not yet shown brilliant results despite the large number of remedies recommended. Internally, quinine, belladonna, and bromide of potash are most worthy of a trial. Quinine is given in powders of one and a half to eight grains (0.1 to 0.5) several times a day, either in capsules or, in the case of smaller children, with chocolate. The earlier this remedy is employed the more prompt is said to be its beneficial influence. Lately the treatment of whooping-cough with antipyrine has been much recommended. Belladonna is prescribed in powders containing one twelfth to one sixth grain (0.005 to 0.01) of the extract of belladonna, giving three to five such powders a day. This remedy has often seemed to the author to diminish the number and violence of the paroxysms. The largest daily dose of sulphate of atropine to be given to children is one sixtieth of a grain (0.001), and even this amount demands in every case caution and watchfulness for the possibility of symptoms of poisoning, such as enlargement of the pupils and dryness of the mouth. Bromide of potash is employed in an aqueous solution in the dose of fifteen to forty-five grains per diem (1 to 3 gm.). Its benefit is probably due to its power to diminish reflex excitability. The same drug employed in an atomizer often has a palliative effect.

If the paroxysms are very violent we may cautiously administer small doses of morphine or codeia. Inhalations of chloroform and ether have also been recommended. The following mixture is a suitable one:

R Chloroformi.....  $\frac{3}{4}$  j (grm. 30);  
 Ætheris.....  $\frac{3}{4}$  ij (grm. 60);  
 Ol. terebinthinæ..... 3 ijss. (grm. 10). M.

Sig. One or two teaspoonfuls to be poured upon a pocket-handkerchief for inhalation.

Finally, considerable success has attended the application of cocaine to the throat and larynx by means of a brush. A solution of ten to fifteen per cent. has a considerable influence in modifying the frequency and violence of the paroxysms. Michael advocates the daily insufflation into the nostrils of powdered benzoin.

Inhalations of various antiseptic remedies have been frequently employed because of the infectious nature of the disease. The practitioner must not expect too much from them, however, although they sometimes act well. A one-per-cent. or two-per-cent. solution of carbolic acid is most frequently employed for inhalation. It may be given several times a day for periods of two or three minutes at a time. Next to this, turpentine and benzine are most to be recommended; of these, twenty or thirty drops are poured upon a sponge previously moistened with hot water. [Farlow and others report marked success from spraying the upper air-passages with a two-per-cent. solution of resorcin.]

For the treatment of the complications and sequelæ of whooping-cough the reader is referred to the appropriate chapters of this book.

## CHAPTER VI.

**BRONCHIECTASIS.***(Bronchial Dilatation.)*

DILATATION of the bronchi is not a separate disease, but it is a result of various affections of the lungs and bronchi. Nevertheless, we will speak of it briefly in this connection since many cases of bronchiectasis present the appearance of quite a characteristic disease.

We distinguish anatomically the cylindrical and saccular bronchiectases.

**Cylindrical bronchiectasis** consists of a uniform dilatation of a bronchial tube, and occurs most frequently in the medium-sized, or rarely in the finer bronchi of one or more lobes of the lung. It is usually due to a long-continued bronchitis, and develops most frequently in cases of emphysema, and also in whooping-cough, measles, and sometimes in phthisis, etc. The primary process is probably always the atrophy which follows the catarrh, and the diminished resistance of the bronchial walls thus occasioned. The dilatation of the lumen of the bronches is produced gradually, partly by the traction of the thorax during inspiration, and still more by the increased pressure in the bronchi due to the frequent and violent fits of coughing, and finally, perhaps, by the constant pressure of the stagnating secretion.

The diagnosis of cylindrical dilatation of the bronchi is only a probable one. We suspect that a bronchiectasis has formed if the conditions are fulfilled which we know lead to it. In the chronic bronchial catarrh of emphysema we judge that there is cylindrical dilatation of the bronchi if the secretion is very abundant and comparatively thin, and separates on standing in a sputa-cup. The dilatation is usually emptied by a severe paroxysm of coughing, such as is apt to occur in the morning if the secretion collects in great quantity during the night. Physical examination usually gives numerous small and medium moist râles, especially in the lower lobes. The respiratory murmur sometimes loses its vesicular character in marked cylindrical bronchiectasis, and has a more indefinite and tubular quality.

**Saccular bronchiectases** are spherical or oval dilatations which are confined to a definite portion of the bronchial tube. They may attain a diameter of several centimetres. The bronchus passes suddenly or gradually into the dilatation, and it is often obliterated so that the bronchiectasis forms a completely closed cavity. The wall of a saccular bronchiectasis loses in great measure the character of a normal bronchial wall. As a rule it is atrophied to a high degree, the atrophy involving not only the mucous glands, but also the muscular fibers, the elastic elements, and even the cartilages, so that the bronchiectasic cavities seem lined with nothing but a thin membrane. In other cases, however, we find hypertrophic processes, which involve the connective tissue of the mucous membrane, and lead to band-like projections and swellings. Finally, ulcerative processes may develop on the inner surface of a bronchiectasis and attack the surrounding lung-tissue, and change the bronchiectasis to a typical ulcerating cavity.

Only rarely, for example in emphysema, do we find a single saccular bronchiectasis surrounded by tolerably normal lung-tissue. Its origin, then, is to be referred to causes like those which have been given above for the much commoner cylindrical bronchiectases. In the great majority of cases we find saccular bronchiectases, singly or in large numbers, surrounded by indurated and contracted lung-tissue. They form one of the complications of "pulmonary contraction" [fibroid phthisis], which is almost always associated with contraction of the pleura. Since Corrigan's day we have with good reason looked upon this con-

traction as the chief cause for their origin. By the gradual shrinking and retraction of the lung, which as a rule has become adherent to the costal pleura, a traction is exerted upon the bronchial walls from without to which they gradually yield. Thus arises the frequent combination of pulmonary contraction with the formation of bronchiectases. This combination is usually unilateral, and involves the whole lung or only one of the upper or lower lobes. This form has been described from a histological stand-point as a chronic interstitial pneumonia, and it has been believed possible to make a sharp distinction between it and the chronic tubercular processes in the lung.

We often see the form of pulmonary contraction in question developing as a result of pleurisy. Laennec first advanced the opinion that in such cases the pleurisy was the primary trouble, and that from it an interstitial inflammatory process attacked the connective tissue of the underlying lung and led to contraction and then to the formation of bronchiectases. In our opinion we must indeed recognize the manifold anatomical and clinical peculiarities of the combination of pulmonary contraction and formation of bronchiectases in question, but aetiologicaly we are unable to separate it from pulmonary tuberculosis (*vide infra*), at least in the great majority of cases. But on the other hand it can not be denied that extensive bronchiectasis is sometimes observed entirely independent of any tuberculous process. In these rare cases the bronchial dilatation seems to be a sequel in most instances of a severe antecedent chronic bronchitis. It is seen, for example, in workmen who are obliged to inhale a great deal of dust. There can be no doubt, however, that the process here finally extends to the lung-tissue, for upon autopsy the parenchyma between the various bronchiectatic cavities is usually not normal, but transformed into a firm indurated tissue. As a rule the disease is mainly limited to one side, involving perhaps the whole lung, or, if only a single lobe, usually the lower one.

The symptoms caused by saccular bronchiectasis alone are derived in part from the result of physical examination and in part from definite peculiarities of the sputum. If great bronchiectatic cavities lie near the chest-wall, they may give the same physical signs that we shall learn to recognize later in the description of tubercular cavities. Bronchiectases lying within the lung, however, are often devoid of definite physical signs, so that at most we may suspect them from other symptoms, like the peculiarities of the sputum. The more abundant the formation of bronchiectases the more does the respiration lose its vesicular character and become harsh and finally bronchial. Inasmuch as there is usually a very considerable secretion of mucus, we generally find, upon auscultation, abundant medium and even coarse moist râles.

The expectoration is, as a rule, very abundant, and it is often raised "by mouthfuls." On standing, it exhibits a distinct division into an upper layer of serum and a lower of pus. It usually has a stale, sweetish odor, but it may be foetid. The diagnosis of the extensive formation of bronchiectases in the lungs is usually quite easy. In order to avoid confounding it with chronic tuberculosis, the following should be especially considered: In bronchiectasis the patient does not present a true cachexia; he is usually somewhat cyanotic and often pale at the same time. The terminal phalanges of the fingers are often clubbed, as in foetid bronchitis. Fever is usually absent, unless there are some special complications. The expectoration is more abundant and more distinctly stratified than is often seen in tuberculosis; and, most important of all, it contains, of course, no tubercle bacilli.

Since bronchiectasis may give rise to a foetid bronchitis, and since, on the other hand, as we have said, foetid bronchitis itself often leads to the formation of bronchiectasis, we can understand the manifold relations and changes which the

two forms of disease described may furnish. If ulcerative processes arise in the wall of a bronchiectasis, they may give rise to hæmoptysis.

The further course of bronchiectases depends, of course, upon the nature of the primary affection. The cylindrical dilatations which arise after a severe bronchitis, as happens in whooping-cough, measles, or typhoid, may in many cases gradually get well; but recovery from saccular bronchiectasis by a process of obliteration, if it occurs at all, is extremely rare. Nevertheless, the course of the disease may be comparatively benign, since the affection often remains circumscribed, and the patient's general strength and nutrition suffer comparatively little from it. Finally, of course, severe symptoms arise, either from insufficiency of the heart, when there is cyanosis, dyspnoea, or œdema, or as a result of emphysema, tuberculosis, gangrene, or extensive lobular pneumonia.

The **treatment** is never directed against the bronchial dilatation as such, but toward its causes or sequelæ. The treatment of bronchiectasis, therefore, coincides with the treatment of chronic bronchitis, emphysema, foetid bronchitis, chronic tuberculosis, etc.

## CHAPTER VII.

### STENOSIS OF THE TRACHEA AND BRONCHI.

#### 1. TRACHEAL STENOSIS.

**Ætiology.**—Stenosis of the trachea may be caused either by diseases in the vicinity of the trachea, or by diseases of the trachea itself. The first-named mode of origin is the more frequent. To this are due all the stenoses of the trachea from compression. Enlargements of the thyroid gland from simple struma and new growths, aneurisms of the arch of the aorta and of the innominate artery, tumors and abscesses in the anterior mediastinum, swelling of the lymph-glands at the bifurcation of the trachea, abscesses on the anterior surface of the cervical vertebrae, etc., may exert so great a pressure on the trachea from without that its lumen is made narrower. Besides the direct action of pressure, in most cases, a gradual atrophy from the pressure and a softening of the rings of cartilage sometimes plays an important part, according to Rose, in the occurrence of stenosis. A collapse of the trachea may arise from this "flaccid softening," which may come on quite suddenly, and may cause many of the cases of sudden "scrofula death."

Changes in the trachea itself leading to stenosis are quite rare. Cicatricial stenosis as a result of syphilitic ulcerations is relatively the most frequent. New growths in the trachea are also to be mentioned, such as polypi and carcinomata, the latter almost always having invaded the trachea from the adjacent parts. Very rarely acute and chronic inflammatory processes like perichondritis lead to a swelling of the mucous membrane sufficient to cause stenosis. In conclusion, we may mention that stenosis of the trachea may be due to the presence of foreign bodies.

**Symptoms.**—If the stenosis is so extreme that there is a real hindrance to respiration, a very striking modification of the breathing occurs. It is difficult and labored, and is performed only by the help of the accessory muscles. Both expiration and inspiration are protracted, long drawn, and accompanied by a loud stridor. In many cases inspiration is more difficult than expiration, so that there is accordingly a preponderating inspiratory dyspnoea, and the number of respirations a minute is diminished. If the entrance of air into the lungs is incomplete

in spite of the lengthening of the respirations, we see an inspiratory retraction of the lower part of the thorax, and sometimes of the throat and the supra-clavicular fossæ. In tracheal stenosis the larynx, however, shows little or no to-and-fro movement on respiration. This fact is of value in diagnosis in distinguishing tracheal from laryngeal stenosis, for in the latter the respiratory movements of the larynx are quite well marked.

We sometimes notice in the pulse during inspiration a marked fall in tension and in the height of the pulse-wave, the *pulsus paradoxus*. With the sphygmograph we can show still more plainly the changes in blood-pressure, which vary quite markedly with the respiration. The frequency of the pulse is usually a little increased, but sometimes it is diminished.

The symptoms of the disease just described may form so characteristic a picture that we can recognize it at the first glance. More precise information as to the seat of the stenosis, or the accurate differentiation of tracheal stenosis from the very similar picture presented by laryngeal stenosis, demands a direct laryngoscopic examination of the larynx and trachea, which, of course, is hardly practicable in a patient with a high degree of dyspnoea.

## 2. BRONCHIAL STENOSIS.

Narrowing of a primary bronchus, which is the only form to be mentioned here, arises most frequently as a result of the presence of foreign bodies. These may enter the air-passages by means of a deep inspiration while eating, or during sleep. We know that foreign bodies get into the right bronchus, which is wider, somewhat more frequently than they do into the left. Stenosis of the main bronchi from pressure also arises from aneurisms of the aorta, mediastinal tumors, enlarged bronchial lymph-glands, etc. Stenosis of the left bronchus from the pressure of the greatly dilated left auricle has been observed in mitral stenosis.

The symptoms are not equally distinct in all cases, and they depend upon the shutting off of the corresponding part of the lung. The dyspnoea is usually very evident, especially in acute cases. The respiratory excursions are much less on the affected side than on the sound side. The percussion-note, indeed, remains clear, but the vesicular respiratory murmur disappears, and instead of it we sometimes hear over the whole side a loud whistling or humming sound, the vibration of which can in some cases be felt by the hand applied to the chest-wall. The vocal fremitus is diminished on the affected side. A vicarious emphysema soon develops in the other lung.

Lobular pneumonia frequently develops as a result of the entrance of foreign bodies into a bronchus, because the agents of inflammation have entered at the same time with these bodies, and, as the expectoration can be evacuated only with difficulty, and hence is more or less stagnant, these irritants can readily establish themselves in it. In stenosis from pressure the character of the disease may of course be modified in many ways by the primary disease.

The **prognosis and treatment** of tracheal and bronchial stenosis depend entirely upon the nature of the primary disease. General statements as to treatment, therefore, need not be given here. A direct mechanical treatment of tracheal stenosis in appropriate cases, such as cicatricial stenosis, may be undertaken according to the different modes of dilatation above enumerated. The methods for removing foreign bodies from the larger air-passages belong to the domain of surgery. The employment of an emetic has met with distinct success in such cases, but it is not without danger, for the foreign body may wedge itself into the glottis during the act of vomiting and result in the danger of instant suffocation.

## CHAPTER VIII.

## BRONCHIAL ASTHMA.

*(Nervous Asthma.)*

BRONCHIAL asthma is a disease clinically well characterized, but ætiologically it is probably not quite a distinct affection. Its chief symptom consists of marked paroxysmal attacks of dyspnoea. The cause of the dyspnoea is not to be sought in any coarse factor that can be demonstrated anatomically, but it is probably due, at least in part, to some abnormal condition of nervous irritation. The chief theories as to the origin of the asthmatic attacks will be given further on. The disease is decidedly more common in men than in women, and it is not very rare even in children.

**Symptoms and Course of the Disease.**—"Nervous" bronchial asthma consists, in its purest form, of attacks of shortness of breath, which come on in persons who are otherwise quite well, with varying frequency and varying duration, partly from some special cause, and partly without any discoverable reason. In the intervals between the attacks the patients are completely well, and do not show the slightest signs of any disease of the respiratory or circulatory organs.

The asthmatic attack either begins quite suddenly, or it is preceded for a shorter or longer period by prodromata. These consist in a general feeling of discomfort, in abnormal sensations in the larynx or epigastrium, sometimes in remarkably frequent gaping, and often in a marked coryza associated with a good deal of secretion and frequent sneezing (compare the relation between many attacks of asthma and diseases of the nose, given below). The attack begins in most cases at night. The patient wakes up with an intense feeling of pressure and anxiety. Sometimes he complains of a feeling of pain in the chest. He has to sit up straight, and in severe cases even to get out of bed. He often hurries to an open window in order to "get air." His expression is anxious; his skin becomes pale and cyanotic, and sometimes is covered with a cold sweat. The respiration, too, is altered in a very peculiar and characteristic way. Both inspiration and expiration are almost always accompanied by a high-pitched whistling sound, audible at a distance. Both respiratory acts are labored, requiring the aid of the accessory muscles. On inspiration, only the upper part of the thorax is elevated to any extent. We see in the neck the inspiratory contraction of the sterno-cleido-mastoids, the scaleni, etc. Still more striking, however, is the labored, panting, long-protracted expiration, during which the abdominal muscles are contracted to a board-like hardness. We therefore recognize the disturbance of respiration in asthma as essentially an expiratory dyspnoea. The frequency of respiration is in many cases normal, or even somewhat diminished, yet we have repeatedly counted thirty or forty respirations a minute.

On physical examination of the lungs during the paroxysm, we find the percussion-note over them normal or even strikingly loud and deep—the "box-tone." The lower boundary of the lung is usually found one or two intercostal spaces lower than normal. We accordingly have to do with an abnormally low position of the diaphragm, with an acute emphysema. On auscultation, whistling and creaking sounds, which quite obscure the vesicular murmur, are heard over most of the lung, especially during the long expirations. In many places, indeed, the respiratory murmur is entirely absent, or we hear only a low whistle on expiration. Toward the end of the paroxysm the noises become deeper and more booming, and sometimes we hear a few moist râles.

In brief paroxysms there may be scarcely any cough or expectoration. In

most, particularly in the tedious, cases, there is, however, a scanty tough mucous expectoration. In this are found, beside the ordinary constituents of simple bronchitic sputum, larger or smaller numbers of very characteristic clumps. These may be yellow or greenish-yellow, or, on the other hand, gray. The yellowish clumps, which are usually very tough, and often consist of a clump of thready matter, represent swollen and fatty-degenerated pus corpuscles, between which are very frequently interspersed a considerable number of pointed octahedral crystals. These crystals were first described by Leyden in the sputum of asthmatic patients, and are usually termed asthma crystals (see Fig. 22). Chemically they are identical with "Charcot's crystals," which are found in the leukæmic spleen, the bone marrow, and the semen, and they probably represent the phosphoric-acid salt of a peculiar base (Schreiner's base,  $C_2H_4N$ ). As soon as the paroxysms cease the number of crystals in the sputum usually begins to diminish rapidly, and it is often possible to observe in them evident tokens of disintegration. Often, also, numerous ciliated epithelial cells are found, in addition to the crystals, in the yellow masses. The gray plugs in the sputum of asthmatic patients consist mainly of clumps of thready mucus, and contain the peculiar "spirals" which were first described by Ungar and by Curschmann. Many of these spiral threads are visible to the naked eye, but others demand the microscope for their recognition, through which they are seen as brilliant forms composed entirely of various sized bands and threads collected in spirals (see Fig. 22). Sometimes a brilliant central thread of small diameter is seen in the midst of the spiral. Around the spirals are found round cells, drops of fat and myeline, epithelium, and, according to Lewy, frequently also numerous epithelial cells from the pulmonary alveoli. As to the precise way in which the spirals and their central thread develop, the question is not yet settled, but it is certain that the spirals represent casts of the minutest branches of the bronchi, and therefore indicate the existence of a peculiar disease of the terminal bronchial twigs (see below). It should be added that sometimes also the microscope reveals in the sputum crystals of oxalate of lime (Ungar) and of phosphate of lime (Lewy).

The pulse is usually accelerated during the asthmatic paroxysm; the bodily temperature is normal, or sometimes even subnormal. In asthmatic patients who have protracted attacks we have repeatedly seen a slight febrile movement up to about  $102^{\circ}$  ( $39^{\circ}$  C.).

The duration of the asthmatic paroxysm is very different in individual cases, as has already been said. Sometimes it lasts only a few hours, but sometimes

FIG. 22.—Asthma crystals and Curschmann's spirals (a, central fiber).

it lasts several days, and even weeks. The attacks of protracted asthma are not very rare. Marked exacerbations and remissions of the disease usually alternate

in them. The frequency of the paroxysms in ordinary asthma also varies exceedingly. Sometimes they come on almost every night, and then there are long pauses of months and years, so that we can not make any general statements as to the course of the disease. Definite recoveries are quite rare; they are most frequent in children.

Although patients with the form of pure essential asthma which we have so far described seem perfectly well in the intervals between the attacks, there is also a symptomatic asthma. This is seen chiefly in patients with emphysema and chronic bronchitis. The term "symptomatic asthma," however, can be used only when the attacks actually show the symptoms of pure asthma, and when the dyspnoea which occurs in them has no relation to the anatomical lesions present. In such cases it is often hard to decide whether the existing emphysema and chronic bronchitis are really the primary disease, or the result of the asthma. There is no doubt but that a secondary emphysema of the lungs may develop as a result of frequent and protracted asthmatic attacks. The attacks of dyspnoea, which come on in chronic affections of the heart and blood-vessels—cardiac asthma (*vide infra*)—depend upon other causes than the peculiar bronchial asthma, and should not be classed with it.

**Theories as to the Origin of Asthma.—Ætiology.**—The peculiarity of the asthmatic symptoms has given rise to numerous theories as to the origin of asthma, yet none of them have obtained general recognition up to the present time. Many authors, like Weber, Störek, and Fräntzel, seek the underlying cause of asthma in an acute swelling of the bronchial mucous membrane, as a result either of a sudden dilatation of the blood-vessels arising from nervous influences or of a very acute catarrh. Wintrich and Bamberger have advanced the theory that asthma consists in a tonic spasm of the diaphragm, by which the diaphragm is kept motionless in a fixed inspiratory position; but it is at once plain that such a condition can at least not play the chief part in the occurrence of asthma, for we can usually feel the respiratory movements of the diaphragm quite plainly during the paroxysm. It should be stated that Riegel, who is the latest champion of the theory of diaphragmatic spasm, is of the opinion that there is not a complete tetanic spasm of the diaphragm, but merely a superexcitation of the phrenic nerve, and that the excursions of the diaphragm are not completely inhibited.

The theory long ago advanced by Trousseau, the chief advocate of which of late is Biermer, is the most probable one, and is now generally accepted, namely, that the spastic nervous element, which is not wholly to be disregarded in any explanation of bronchial asthma, consists of a tonic spasm of the muscles of the smaller bronchi. The tonic contraction of the smaller bronchi explains the whistling sounds that are heard. A marked hindrance to respiration is set up which can be more easily overcome by the inspiratory suction of the thorax than by the expiratory pressure. Since the latter acts not only upon the alveoli, but also upon the lesser bronchi themselves, the closure of the bronchi upon expiration is still more marked. The air which is drawn into the alveoli can consequently get out again only imperfectly, and this explains the expiratory dyspnoea, the emphysema that soon occurs, and the low position of the diaphragm. The acceptance of this theory of bronchial spasm also readily explains the often sudden onset, and just as sudden cessation, of the asthmatic attack.

If we inquire further, however, into the cause of the occurrence of the bronchial spasm, only a very indefinite answer can be given; for little is said by answering that asthma is a neurosis of the vagus. Many facts make it very probable that the spasm is of reflex origin, at least in many cases. Leyden has expressed the suspicion that the irritation of the mucous membrane by the pointed crystals, which he discovered, gives rise to the spasm. It may be said in oppo-

sition to this, however, that the "asthma crystals" are sometimes found in the sputum of patients with emphysema who have no asthmatic symptoms, and also that in asthmatic patients the severity and duration of the attacks stand in no constant relation to the number of the crystals. Nor can the above-pictured spirals be regarded as the cause of the paroxysms of asthma, since they likewise occur in other diseases of the minutest branches of the bronchi—for example, they are not very rare in croupous pneumonia.

The fact lately corroborated by numerous observations by Voltolini, B. Fränkel, Hack, and others, is very important—namely, that the asthmatic paroxysm is sometimes of reflex origin, starting from some disease of the nasal mucous membrane. We find quite often, for instance, that asthmatic patients are suffering from chronic diseases of the nose, like chronic catarrh, nasal polypi, and especially the enlargement of the so-called erectile bodies of one or more turbinated bones, and that after their removal the asthma disappears. In this connection may be cited the noteworthy fact that many asthmatic patients have an attack brought on by certain odors, for example, at the smell of freshly roasted coffee, or of ipecacuanha. Trousseau, who suffered from asthma himself, always had an attack on smelling violets. It is doubtful whether a pure bronchial asthma can have a reflex origin from other distant organs. The connection between asthma and diseases of the pharynx, or hypertrophy of the tonsils, is extremely probable in some cases, but the statements as to the occurrence of asthmatic paroxysms in diseases of the stomach ("dyspeptic asthma"), of the intestine, or of the female sexual organs, are to be taken only with great reserve. We usually have to do here with a confusion between pure asthma and other conditions of dyspnoea—nervous dyspnoea, conditions of cardiac weakness, etc.

In a large number of cases—which seem to us to be most characteristic—the disease can be explained, in our opinion, only by the hypothesis of a peculiar primary disease of the bronchial mucous membrane, particularly affecting the terminal twigs of the smallest bronchi, and whose special feature, somewhat like the spasm of the glottis in whooping-cough, consists in the occurrence of a reflex bronchial spasm. The whole type of the disease and the peculiarities of the expectoration, the spirals, and crystals, furnish unequivocal testimony for this theory of asthma. Curschmann therefore claims that the anatomical basis of these cases is an exudative bronchiolitis. We think that "asthmatic bronchiolitis" is the most fitting name for such cases of asthma as are not found to be dependent upon disorders of the nose or similar causes.

The observation, often made, that many asthmatic patients have attacks only when in certain places, and are quite free from them in others, is very remarkable. They sometimes have an attack at every change of place. In conclusion, it may be mentioned that in some cases a distinct hereditary predisposition to asthma has been observed, and that asthma sometimes occurs in families with a general neurotic tendency.

**Diagnosis.**—This is usually easy if we pay careful attention to all the symptoms and to the whole course of the disease. Other conditions which may lead to dyspnoea are of course to be excluded by a careful examination of the chest. Attacks of spasm of the glottis and of paralysis of the openers of the glottis are to be differentiated from bronchial asthma by the predominance of inspiratory dyspnoea as well as by other signs. And in cardiac asthma and the manifold varieties of respiratory spasm and neurotic angina, such as are seen especially in hysteria, not only are the other attendant symptoms different from those seen in genuine bronchial asthma, but the very dyspnoea itself is usually of quite another variety.

**Prognosis.**—There is hardly ever any immediate danger to life even in the most intense asthmatic paroxysms, but permanent recovery is rare, since even after long intervals the attacks may finally return. The chief danger in severe and protracted cases lies in the development of a pulmonary emphysema with its further consequences.

**Treatment.**—In every case of asthma the first thing to be thought of is whether there is not a definite cause whose removal may cure the disease. In this connection we should examine the nose carefully, since numerous observations have recently shown that a previously existing asthma may permanently disappear after the treatment of some nasal disease which may be present, like the removal of polypi, the destruction of the erectile bodies by the galvano-cautery, etc.

If we can not satisfy the causal indication in this way, we should always try next a remedy which must pass for a direct specific against certain forms of asthma—iodide of potassium. In doses of twenty to forty-five grains a day (grm. 1.5-3.0), which can be increased if necessary, this usually causes a rapid improvement, which of course is not always, although it is frequently, permanent. If iodide of potassium has been used in vain, we must turn to the other remedies which have been employed against asthma, although their action is often quite uncertain. We may mention here the nitrite of sodium (two parts in one hundred and twenty of water, two to three teaspoonfuls a day), and nitro-glycerine, which has an analogous action (twenty drops of a one-per-cent. alcoholic solution in six and a half ounces (grm. 200) of water, a tablespoonful two or three times a day); also quinine, bromide of potassium, belladonna, atropine, arsenic, etc. In some cases pneumatic treatment, such as the inhalation of compressed air, has been successful, and sometimes, too, electricity (galvanization and faradization of the neck), or hydrotherapy, has been claimed to give relief. Change of climate may be of distinct service. Many patients bear the sea-air well, while with others mountain traveling exerts a favorable influence.

In severe cases a special symptomatic treatment of the attack itself is often necessary. Narcotics are without doubt the most effective, especially chloral and morphine. In severe attacks we can not avoid injections of morphine, but we must always be cautious in order that the patient may not form the habit of using this to excess. Germain Sée has lately strongly advocated inhalations of pyridin. Of this, about one drachm (4 to 5 grm.) is shaken into a saucer and the fumes are inhaled three times a day for fifteen to thirty minutes. Inhalations of chloroform and ether are also much employed. Among other useful remedies and devices we may mention mustard plasters to the chest and calves, putting the hands and feet into hot water, inhalations of nitrite of amyl, inhalations of turpentine or ammonia vapor; also the often-used fumigation with saltpeter paper—unsized paper dipped in a concentrated solution of nitrate of potassium and dried. The stramonium cigarettes to be had in most drug-stores are much praised; or the patient may smoke stramonium or belladonna leaves which have previously been dipped in a solution of saltpeter and then dried. Among internal remedies we may mention tincture of lobelia, formerly much used, and also the remedy lately employed by Penzoldt, the tincture of quebracho, a tablespoonful pure or in some mucilaginous vehicle.

[Potassic iodide is more likely to prevent recurrence if it is given continuously, for several months at least, and it should not be thrown aside as useless until it has been pushed to the limit of toleration without avail. A convenient form of administration is in saturated aqueous solution, a minim of which represents about a grain of the drug.

The syrup of hydriodic acid may be substituted for potassic iodide in cases

of intolerance of the latter. *Grindelia robusta*, a drachm of the fluid extract three or four times a day, serves sometimes to prevent recurrence of attacks. Marked alleviation of the paroxysms is often obtained from the inhalation of fifteen to thirty drops of the iodide of ethyl.]

## SECTION IV.

### DISEASES OF THE LUNGS.

#### CHAPTER I.

#### PULMONARY EMPHYSEMA.

(*Alveolar Ectasis. Increased Volume of the Lungs.*)

**Nature and Etiology of the Disease.**—Pulmonary emphysema, the abnormal inflation of the lungs, is one of the commonest pulmonary affections. It either develops in separate parts of the lung, in which case it is subordinate to other pathological changes which co-exist in the lungs, or it involves almost the whole extent of both lungs, and then presents the symptoms of a characteristic affection, which it is usually easy to recognize.

The essence of pulmonary emphysema, the condition from which most symptoms are immediately derived, is the loss of elasticity in the lungs. If we compare the sound lung with its normal elastic force to a new and very tense rubber band, the emphysematous lung must be compared to an old and lax band that is stretched and pulled out. We therefore see why the emphysematous lung takes up a greater space than the sound one, for, on account of its lack of elasticity, it can no longer contract to its former volume. We may thus call emphysema a permanent inspiratory distention of the lung from which it can no longer return to its expiratory condition. If we open the thorax of a subject with normal lungs, they contract, as is well known, but the emphysematous lungs remain in their inflated condition after the thorax has been opened.

If we inquire into the factors which cause this loss of elasticity in the lung, we find that they are the same kind of influences which tend to diminish the elasticity of any other elastic body. As a rubber band, by much pulling and stretching, gradually gets longer and less elastic, so the lungs, as a result of their abnormally frequent and severe distention, gradually become inelastic and emphysematous. The normal traction of inspiration, which is continually making new demands on the elastic powers of the lungs, finally leads to a loss of elasticity in them. In advanced age most lungs become more or less inelastic. The lungs of an old man are like an elastic band, which has done its work for years but which has finally become yielding. We therefore class the emphysema of the lungs in old age rather among the states of involution such as develop in almost all organs in advanced life, than among special pathological changes. We distinguish, moreover, most of the lungs with senile emphysema from other emphysematous lungs by the fact that their volume as a whole is not increased, but is rather diminished below that of the healthy lung, since we find in them the extensive atrophic processes of old age.

The condition becomes pathological, however, if the elasticity of the lung is deficient in earlier years and without exposure to the action of the special injurious influences which will soon be mentioned. In such cases of emphysema,

developing in middle life or even in youth, the idea of a congenital weakness of the elastic elements in the lungs can not be set aside. It probably consists in a quantitative or a qualitative defect of the elastic tissue. Some observations seem to corroborate the statement that a disposition to emphysema may be present in several members of the same family.

If a lung whose elasticity is previously subnormal can not persistently satisfy the ordinary demands upon it, a normal lung, on the other hand, also loses its elasticity if the demands made upon it are greater than it can perform. This is the reason why pulmonary emphysema is in part considered a disease arising from the occupation. We mean here not only those influences which lead to chronic bronchitis and thus later to emphysema (*vide infra*), but more especially the abnormal demands upon the lungs in all those callings which necessitate severe physical labor. We must not only regard the deeper and more rapid respirations, but also the increased pressure on expiration to which the lungs are often exposed in the raising of heavy weights, etc. This explains the great frequency of emphysema in the laboring classes, and also its greater frequency in men than in women. Beside this, we must add that in certain callings, like glass-blowing and horn-blowing, the overstraining of the lungs is much more direct. In all such cases emphysema may be termed simply a premature exhaustion of the lungs.

In very many cases emphysema develops as a result of other diseases of the lung, and especially as a result of chronic bronchitis. Dry catarrh of the middle and finer bronchi when of long duration leads, as a rule, to pulmonary emphysema. The abnormal mechanical influences to which the lungs are thus exposed act both in inspiration and in expiration. Since the entrance of air to the alveoli is rendered more difficult by the swelling of the mucous membrane in the smaller bronchi, abnormally deep and strong inspirations are necessary, with a marked expansion of the alveoli, in order to draw a sufficient quantity of air into the alveoli. The alveolar walls are therefore exposed to an abnormal traction at each inspiration. On expiration, a pressure from within, which is perhaps even more injurious, acts on the alveoli. The ordinary expiration, which usually needs only the elastic power of the lungs, is not sufficient in chronic bronchitis to drive the air out of the alveoli through the narrowed bronchi. Thus arise the difficulty and delay in expiration which are present in chronic bronchitis, and which lead to the active participation of the muscles of expiration, the abdominal group of muscles. On forced expiration, however, the pressure does not act simply upon the contents of the alveoli, but much more upon the smaller bronchi themselves. The channel of exit for the air from the alveoli, therefore, becomes still narrower. Since the air can not escape, the pressure within the alveoli is raised by the efforts at expiration, and the alveolar wall is thus again abnormally expanded. The cough, which is often present in chronic bronchitis, is a further factor, which acts in a precisely similar injurious fashion. The attacks of coughing begin with a forced contraction of the muscles of expiration, which follows the closure of the glottis. Until the glottis opens, therefore, the lower parts of the lung especially are put under strong pressure. The air in them, which can not escape outward, is driven into the upper parts of the lung, and there leads to expansion of the alveoli, and finally to emphysema.

We accordingly see that a number of injurious influences co-operate in the gradual development of emphysema from chronic bronchitis, and that, sooner or later, these influences have as their result the gradual dilatation of the lungs. Here, too, we must bear in mind the individual differences in the resisting power of the lungs.

Conditions precisely similar to those in chronic bronchitis occur in other dis-

cases, and lead in like manner to pulmonary emphysema. We very often see the development of emphysema in severe and persistent whooping-cough. The worst factor here, besides the existing bronchitis, is the frequent paroxysms of coughing. We have already mentioned, in the description of bronchial asthma, both the acute emphysema, which occurs during the attacks, and the final development of a permanent emphysema.

In conclusion, we must here consider a theory advanced by Freund, which would make the development of an emphysema dependent upon a "primary rigid dilatation of the thorax." It is indeed conceivable that from certain pathological changes in the costal cartilages, as Freund claims, a thorax, which had become rigid in the position of inspiration, might exert a constant abnormal traction on the lungs and so give rise to an emphysema. The occurrence of this hypothetical primary disease of the cartilages, however, has up to the present time not been established. It is rather considered by the majority of authors as a secondary change, developing as a result of emphysema or else simultaneously with it. On the other hand, it is certainly remarkable that we sometimes observe in children the "emphysematous habit" of the thorax and neck, which will be more fully described further on, and that in fact in such children we can often discover early in life a beginning emphysema.

Besides the already described essential or substantial emphysema, which is a special disease attacking both lungs uniformly, we distinguish a so-called vicarious or complementary emphysema. If, by any disease, certain portions of the lungs are incapacitated in their functions, the parts which remain healthy must then assume the whole business of respiration. They become excessively expanded on inspiration, and as a result they become emphysematous. Thus we see emphysema of the upper lobes in affections of the lower lobes. Emphysema of one lung is most frequently observed clinically when the other lung is extensively diseased, especially in unilateral chronic contractions of the lungs and pleura, usually seen in tuberculosis. Vicarious emphysema may also be confined to quite small portions of the lung, but then it is merely of pathological and not of clinical interest.

**Pathological Anatomy.**—As we have seen, the actual abnormality of the lung in emphysema is not due to a pathological change, but to a change in its physical conditions. The loss of elasticity of the lung is shown in its greater volume, in its lack of contractility, and in its persistence in a position of inspiration.

The single alveoli are of course just as much expanded as the whole lung, but their walls show at first no histological changes. We have here, then, a condition which Traube has called "increased volume of the lungs," and has distinguished from the "pulmonary emphysema" proper. This distinction is without doubt justified anatomically, but clinically it can not well be maintained. As the distention is constant, the alveolar walls can not withstand the constant traction and pressure. This leads to progressive atrophy of their tissue from pressure—that is, it leads to a real disappearance of the elastic elements of the lung. The atrophy begins quite gradually. The partition-walls of the alveoli are first perforated, and then they partly or wholly break down. The neighboring alveoli run more and more into one another, and thus finally arise alveolar ectasis and infundibular ectasis, which can be made out with the naked eye, and which may attain a diameter of five or ten millimetres or more. If single air-bubbles enter the interlobular, interstitial, or subpleural connective tissue, which may happen perhaps in severe fits of coughing, we speak of an interstitial or interlobular emphysema, in distinction from the ordinary vesicular or alveolar emphysema.

The tissue atrophy in the septa of the alveoli affects not only the elastic tissue, however, but it also affects the branches of the pulmonary capillaries in the alveolar walls. The affection of the elastic tissue adds no new conditions to the dis-

turbed functions of the emphysematous lung, which we have just described. The destruction and final atrophy of the pulmonary capillaries, however, is the second important factor in the pathology of pulmonary emphysema, for, with the destruction of so great a part of the vascular area in the lungs, the outflow from the right side of the heart is considerably lessened. There must therefore necessarily be a stasis in the pulmonary arteries and the right side of the heart, and the right side of the heart can overcome the increased resistance only by increased work, and thus in every chronic pulmonary emphysema there finally arise a dilatation and consecutive hypertrophy of the right ventricle with their further consequences.

#### SYMPTOMS AND COURSE OF THE DISEASE.

**General Course of the Disease.**—Although a pulmonary emphysema may sometimes, as in whooping-cough, develop in a comparatively short time, still its course is always very chronic. In most cases the origin of the disease is quite gradual, as in all those cases in which an emphysema develops from a chronic bronchitis, an asthma, or as a result of some injurious occupation. The symptoms gradually and insidiously associate themselves with those of the chronic bronchitis.

The symptoms of emphysema usually begin in middle or advanced life, but marked emphysema may occur in youth and childhood. The disease always lasts for years, unless some [fatal] intercurrent disease arises.

The objective and subjective symptoms are due either to the chronic bronchitis, which very often co-exists, or to the emphysema itself. Not only is the bronchitis, as we have seen above, very often the cause of emphysema, but, on the other hand, the development of a chronic bronchitis is greatly favored by the circulatory disturbances in the lung associated with emphysema. Thus the two diseases, emphysema and chronic bronchitis, are closely connected clinically.

Bronchitis causes its well-known symptoms—cough, expectoration, moderate dyspnoea, and a feeling of pressure in the chest. The bronchiectases, which are often gradually formed, especially in the lower lobes, may lend a peculiar stamp to the cough and expectoration (see page 165). Emphysema increases the patient's dyspnoea to a degree which can never be caused by chronic bronchitis alone. The emphysematous lungs soon become incapable of satisfying any extraordinary demands of respiration. Many patients are only slightly conscious of the difficulty in breathing so long as they keep quiet, but whenever they make a trifling physical exertion, go up-stairs, or take a little longer walk than usual, the dyspnoea comes on.

The variations in the intensity and extent of the bronchitis correspond to the frequent and quite marked variations in the patient's feelings. These variations depend upon the condition of the patient, his external circumstances, and the possibility of his taking care of himself; the change of seasons, too, has an influence on him. In pleasant weather many patients live in tolerable comfort, but autumn and winter bring an increase of all their symptoms with the increase in their bronchitis.

The last stage of the disease is characterized by the appearance of a disturbance of compensation in the heart. We have seen above that the cause of the impairment of the pulmonary circulation, and of the resulting hypertrophy of the right ventricle, is the closure of numerous pulmonary capillaries. A further reason for the impairment of the circulation comes from the disturbance of respiration itself, since the influence of the respiratory movements on the circulation is well known. The appearance of a marked disturbance of the circulation may be deferred for some time by the increased efforts of the right ventricle. The

cyanosis of most patients is due solely to incomplete oxidation and to the blood-stasis which extends backward from the right side of the heart into the veins of the body. Finally, however, the right ventricle becomes more and more feeble, the stasis in the veins increases, œdema of the extremities and transudation into the various cavities of the body ensue, and after long suffering the patient succumbs to dropsy.

Emphysema is frequently combined in its later stages with other chronic diseases. Pulmonary emphysema with its sequelæ is seldom found at the autopsy as a single lesion, but we discover in the cadaver co-existing disease of the heart, the blood-vessels, or the kidneys. Pulmonary tuberculosis is often a final development in emphysema, but it is usually of the chronic indurated form, and is not very extensive.

**Physical Examination.** 1. *Inspection.*—In many patients we can detect the disease with considerable confidence at the first glance; we are therefore justified in speaking of an emphysematous habit. The patients are usually quite well nourished, at least in the early stages of the disease, and are often rather corpulent. They appear plump or even somewhat bloated, and their faces are more or less markedly cyanotic. The configuration of the neck and thorax is especially characteristic. The neck is usually short and compressed; the sterno-cleido-mastoid muscles, which have to act as auxiliaries in inspiration, are tense and hypertrophied. The inspiratory contraction of the scaleni may also be seen and felt. The veins in the neck are visibly dilated, and in severe cases are swollen to thick blue cords, and we sometimes see in them evident undulating or pulsating movements. The thorax is rather short, but broad and strikingly deep—the “barrel-shaped thorax.” The intercostal spaces are narrow, and the lower ribs move only a little downward. The epigastric angle is therefore obtuse, and sometimes becomes almost a straight line. The respiratory movements are almost always accelerated in severe cases. Inspiration becomes short and labored. The excursions of single ribs are therefore slight, and the thorax is raised rigidly and more as a whole. Expiration is visibly prolonged. There may be a noticeable retraction of the intercostal spaces on inspiration in the lower and lateral portions of the thorax.

This characteristic form of the thorax in emphysema is regarded as a constant inspiratory position of the ribs, and corresponds to the permanent inspiratory dilatation of the lungs. The peculiar rigidity of the thorax is probably due to the changes in the costal cartilages already described, which, according to Freund, are primary. In many cases the emphysematous form of the thorax gradually develops in the course of the disease, but in other cases it seems to depend on some original predisposition (*vide supra*) to the disease.

In conclusion, we must state that the above description corresponds to the typical form of emphysema, from which we may have many deviations. In the paralyzed thorax, for instance, we may meet with a high degree of essential emphysema of the lungs, which has often given rise to errors in diagnosis.

2. *Percussion.*—Percussion gives very decided results in the diagnosis of pulmonary emphysema. We find the inferior border of the lungs one or two intercostal spaces lower than under normal conditions, corresponding to their permanent inspiratory inflation. Clear pulmonary resonance on the right front in the line of the nipple extends to the lower border of the seventh, and sometimes of the eighth rib. On the left front it extends to the fifth or sixth ribs, so that the cardiac dullness is lessened. The area of cardiac dullness can often not be made out at all; or at most, on strong percussion, it is made out in a limited extent as relative dullness. The pulmonary resonance extends on both sides in the back to the first or second lumbar vertebra. This condition on percussion in emphysema,

however, is frequently altered, because other conditions, like passive congestion of the liver, meteorism, and ascites, may be present at the same time, and push up the diaphragm. Thus the detection of emphysema by percussion is made decidedly difficult.

Qualitative changes in the percussion-note may be entirely wanting in emphysema. The pitch is sometimes remarkably loud and deep—the “box-tone” [tympanitic resonance]; but in other cases, especially in the back, we find it somewhat raised. This may depend in part upon the poor vibratory conditions in the rigid chest-walls, but in other cases it is caused by the retention of an abundant secretion in the lower lobes.

The detection of dilatation and hypertrophy of the right ventricle by percussion is in many cases uncertain, because the lungs cover the heart. A positive result can be obtained only by carefully defining the relative cardiac dullness. The frequent epigastric pulsations in emphysema, and also the marked undulating and pulsating movements in the jugular veins, are to be regarded as quite certain signs of dilatation of the right side of the heart.

3. *Auscultation*.—The characteristic auscultatory sign of emphysema is the prolonged expiration. As a flabby rubber band, when it is stretched and then let loose, no longer snaps back quickly and strongly, so the emphysematous lung, when it has been stretched in inspiration, comes back again only slowly. We hear with it a somewhat aspirated, sonorous sound, which plainly exceeds the vesicular inspiratory sound in duration. The vesicular murmur itself often undergoes a modification in pulmonary emphysema. It sounds exaggerated, and very shuffling, or in other cases it is rougher and more indefinite. In a high degree of emphysema the vesicular respiration is sometimes very low and obscure, because the inspiratory current of air is reduced to a small amount in the lungs, which are already excessively dilated. In many cases we hear rhonchi beside the respiratory murmur, dry whistling, buzzing, and creaking sounds on inspiration and expiration. If cylindrical bronchiectases have already formed, we hear, especially over the lower lobes, numerous small and medium moist râles, but no sonorous rhonchi. The rhonchi may wholly conceal the respiratory sounds. With a marked retention of secretion we sometimes hear nothing but a low, suppressed, rattling sound.

In the heart the sounds are usually rather low, because it is covered by the lung. The “accidental systolic sound in emphysema” at the apex, described by some writers, we have heard much less frequently when the valves were intact than we should expect after the statements relating to it. The pulmonic second sound is, as a rule, markedly accentuated, as a result of the stasis in the pulmonary circulation.

The diminution of the expiratory pressure in emphysema may be measured with the manometer, or with Waldenburg’s “pneumatometer.” The normal expiratory pressure of 110 to 130 millimetres sinks in emphysema to 100 or 80 millimetres. As we should expect, the spirometer shows a diminution of the vital lung capacity, which can be readily explained. The normal lung capacity of about 3,500 cubic centimetres falls to 2,000 or 1,000 cubic centimetres.

#### OTHER SYMPTOMS IN THE LUNGS AND IN OTHER ORGANS.

In regard to the other symptoms in the lungs we have only a little to add to what has already been said. The intensity of the cough naturally varies in individual cases according to the degree of the existing bronchial catarrh. Many patients are troubled by a dry cough, while others have abundant expectoration. There is nothing characteristic of emphysema in the composition of the latter.

All the kinds of sputa which are found in the different forms of chronic bronchitis are also found in pulmonary emphysema. The dyspnoea, whose predominant expiratory character we have already mentioned, increases in advanced cases to a most marked degree. Sometimes the increase shows itself by the appearance of distinct asthmatic attacks. These are often really to be regarded as a symptomatic bronchial asthma, of nervous origin, but, on the other hand, we must not overlook the fact that a temporary increase of the bronchitis, retention of secretion, and cardiac failure, may also excite attacks of dyspnoea, which can not properly be termed asthma.

The important changes in the heart resulting from emphysema have already been described. The exhausted right ventricle can no longer overcome the increased resistance in the pulmonary circulation. The difficulty of respiration is still greater, from the passive congestion of the pulmonary vessels. The skin becomes still more cyanotic, and finally oedema and general dropsy develop. The failure of compensation is evident by the lessening of the pulse, its increased frequency, and sometimes by its irregularity. The difficulty of an objective examination of the heart in emphysema has been spoken of above.

The appearances of blood stasis in the internal organs are shown especially in the liver and the kidneys. The liver is swollen, and its increase in size (the liver of passive congestion) can frequently be made out by percussion or palpation. The pains in the region of the liver, of which many patients complain, are perhaps sometimes due to the stretching of the capsule of the liver, but they are probably more often muscular pains excited by the frequent coughing.

In the kidneys the effect of stasis is first shown by a diminished excretion of urine. The urine is more scanty in amount, more concentrated, of a higher specific gravity, and of a darker color. It generally gives an abundant sediment of urates, and may contain a small amount of albumen. Microscopically, are discovered a few hyaline casts, and a few red and white blood-corpuscles. It is evident that this diminished activity of the kidneys favors the development of dropsy.

The spleen is not infrequently found congested at the autopsy. The evidence of this, however, is often uncertain during life, for percussion of the spleen is difficult on account of the emphysema, and palpation is difficult from the swelling of the body.

Gastro-intestinal symptoms may be present in emphysema. The appetite seldom remains good throughout the disease. Many patients suffer from chronic constipation; and more rarely there is a tendency to diarrhoea.

Fever is not present in simple pulmonary emphysema. Every fever which exists for a long time depends on other complications, like severe bronchitis, pneumonia, or tuberculosis.

**Complications** of emphysema with other chronic diseases are frequent. The old opinion that emphysema and tuberculosis, and emphysema and chronic heart disease, were antagonistic to each other is entirely false. These complications are not very rare. We may also mention the complication with general arterio-sclerosis and with chronic nephritis, especially the contracted kidney. Among acute diseases we must mention croupous pneumonia, which is not very rare in emphysema, where it must always be regarded as a dangerous combination.

The **diagnosis** of emphysema can be made directly from the results of the physical examination, and usually presents no difficulties. It is obscure only when the patient is not examined till the final stage of dropsy. Then it may be very hard to avoid confusing it with forms of heart disease, like primary hypertrophy, myocarditis, or mitral stenosis, or with contraction of the kidney.

**Prognosis.**—Pulmonary emphysema of acute origin, like that resulting from whooping-cough and analogous affections, may be recovered from in many cases,

but otherwise, as regards the final curability of the disease, the prognosis is wholly bad. The duration of the disease and the intensity of the symptoms are of course very different in individual cases. Here almost everything depends upon the circumstances in which the patient is placed. With sufficient care the disease may be tolerably well borne for many years, but without it the first symptoms of respiratory and cardiac insufficiency appear much earlier.

**Treatment.**—Since emphysema itself is only slightly amenable to treatment, most of our therapeutic remedies are directed to that accompanying condition upon which the greater part of the symptoms depend—to the chronic bronchitis. If we succeed in improving this, or even in wholly removing it, we always obtain a distinct improvement in all the patient's symptoms. The therapeutic remedies mentioned in the description of chronic bronchitis are therefore of frequent use in emphysema.

In the first place, we must seek the best hygienic conditions for the patient, and remove him from all injurious influences, such as dust, bad air, and work requiring physical exertion. In dry catarrh we should use the alkaline mineral waters, and when there is abundant mucous secretion the balsams, such as turpentine internally and by inhalation. The most valuable expectorants are apomorphine, liquor ammonii anisatus, and senega. Their action, of course, too often fails of the desired result, so that we frequently have to change our remedies. When there is a troublesome cough, disturbing the sleep, we can not dispense with narcotics, like morphine or Dover's powder. If severe dyspnoea comes on, we may try to obtain relief by mustard plasters to the chest, or by immersing the hands and feet in hot water. With asthmatic attacks we may try iodide of potassium, beside the other remedies mentioned for asthma. Here, too, we must finally resort to narcotics.

We must carefully watch the condition of the heart, and use digitalis when there are signs of beginning disturbance of compensation and the pulse grows small and irregular, and this drug may prove very useful. If symptoms of dropsy set in, we may sometimes prescribe diuretic remedies, like juniper-tea, or acetate of potassium, besides digitalis. We also try to strengthen the heart by wine, camphor, benzoic acid, or other stimulants.

Besides the purely symptomatic treatment thus described, the attempt has been made to meet the causal indications in emphysema, and especially to aid the patient in expiration, and thus to improve the power of the lung to contract, where it is possible. To this end Gerhardt has recommended assisting expiration mechanically by compression of the thorax. This compression must be done methodically by another person,\* about five or ten minutes every day, by the aid of both hands laid flat on the lower lateral portions of the thorax. The effect of this manipulation in diminishing the dyspnoea and making expectoration easier is in many cases very satisfactory.

The employment of the pneumatic treatment has also become quite general, especially since the introduction of Waldenburg's portable apparatus. The expiration into rarefied air, which meets the causal indication, may procure great relief for the patient in many cases, and sometimes, too, result in an improvement of the emphysema which can be demonstrated on physical examination. Inhala-

\* One of my patients at the polyclinic in Leipzig made himself a very simple but very effective apparatus for producing this compression of the thorax on himself by the aid of two small boards, which are firmly fastened together at one end by a long cord. These boards, which are furnished with a piece of wood at this end fitted to the wall of the chest, are laid flat on the two sides of the thorax so that their free ends can project forward some six inches or a foot, and serve as a one-armed lever. By pressing them together the patient himself can thus, without any strain, exert a considerable pressure on his thorax with each expiration.

tions of compressed air are also employed when there is severe bronchial catarrh. Still, too much must not be anticipated from pneumatic treatment.

## CHAPTER II.

### PULMONARY ATELECTASIS.

(*Compression of the Lungs. Aplasia of the Lungs in Cases of Kyphoscoliosis.*)

**Ætiology.**—Atelectasis of the lungs is a condition directly opposed to emphysema. While in the latter the lungs are abnormally inflated, in the former they are abnormally collapsed. The air has disappeared from the alveoli and lesser bronchi, and in the most advanced cases even from the larger bronchi. The atelectatic portions of the lung are not altered histologically, but are changed to a firm tissue, deprived of air—the so-called splenization or carnefaction.

The atelectasis of the new-born is due simply to deficient respiration and to the consequent imperfect entrance of air into the lungs. In weak children, who die soon after birth, we often find the lower lobes wholly or in part in a fetal, uninflated condition—that is, atelectatic. By artificial inflation we can readily expand the lungs to their normal extent.

Acquired atelectasis occurs in two ways. We may mention, as the first and most frequent ætiological factor, the plugging of the smaller bronchi. If a complete closure of a bronchus arises from the accumulation of secretion, as may easily happen in the narrow bronchi of children, the air can no longer enter, on inspiration, into that portion of lung supplied by the plugged bronchus. The air which is shut up in it is gradually absorbed by the blood. The adjacent parts of the lung expand, and the portion that is excluded from respiration collapses, leaving a circumscribed pulmonary atelectasis, usually rich in blood but devoid of air. Such atelectases, in greater or less number and extent, are very often found in the bodies of children who have suffered from severe bronchitis, especially after measles, whooping-cough, or diphtheria. Beside the direct action of the plugging of the bronchus, the weakness of the respiratory movements and the cough, conditional upon the general state of the disease, play a significant part.

The second very frequent and important cause of pulmonary atelectasis is compression of the lung. In all the diseases which diminish the space for the expansion of the lungs, the lungs are pressed together from without to a greater or less extent, whereby the air is pressed out of them. Thus arise the atelectases from pressure in pleuritic effusion, hydrothorax, pneumothorax, in marked cardiac hypertrophy, pericardial effusion, and aneurism of the aorta. Atelectasis of the lower lobes also arises in the same way from great upward pressure on the diaphragm by ascites, meteorism, abdominal tumors, etc.

That form of pulmonary atelectasis which arises from deformities of the thorax is of great practical importance. In severe kyphoscoliosis, the half of the thorax corresponding to the convexity of the vertebral column is much narrowed. The lungs are materially hindered in their expansion, and even in their growth, if the deformity occurs in youth. This is called "aplasia of the lungs," a condition which may give rise to grave results (*vide infra*).

**Symptoms.**—In the majority of cases the appearances in atelectasis are subordinate to the symptoms caused by the primary disease. This is especially the case in most of the atelectases from pressure, although the most dangerous factor lies in the compression of the lung.

The atelectasis of the lungs developing as a result of diffuse capillary bronchitis,

especially in children, can of course not be detected by physical examination until it is of great extent. The respiration, in extensive formation of atelectasis, often shows a very striking and characteristic deviation from the ordinary type, especially when the atelectasis develops in the lower lobes. It is accelerated and labored, and is performed chiefly by the upper and anterior portions of the thorax. In the lower portions we see marked inspiratory retractions, which are caused in part by the external pressure of the air, and in part correspond to the forced contraction of the diaphragm.

Physical examination can, of course, reveal abnormal conditions, especially dullness on percussion, only when the atelectasis is extensive. Dullness, however, is usually hard to make out in children. Auscultation gives signs of existing bronchitis; and sometimes, too, with more extensive consolidation, there is bronchial respiration. In other cases, as may be easily seen, the respiratory murmur is much diminished or wholly absent. As we can perceive, the physical signs of atelectasis are not really distinguishable from those of pneumonia, especially of lobular pneumonia. In fact, a sharp boundary between atelectatic nodules and nodules of lobular pneumonia in the lung can not be drawn clinically.

Aplasia of the lungs in kyphoscoliosis demands a special description, because it is of great practical significance. Many patients with kyphoscoliosis may live for years without special respiratory disturbance. More careful observation, of course, usually shows a somewhat labored and hurried respiration, but the patients have not paid much attention to it. In other cases the difficulty in breathing is more noticeable. The person affected is incapable of any severe physical exertion; he always feels short of breath, and often suffers from cough and expectoration. In the cases first mentioned, however, which for years have had little or no trouble, disturbances in respiration sometimes come on quite suddenly. They may develop as a result of a mild bronchial catarrh, and they also frequently arise without any special cause, and may attain a very threatening degree. The condition may improve, or it may lead to comparatively speedy death. Examination of the lungs during life usually shows nothing but the signs of an extensive bronchitis. By careful percussion we may quite frequently detect an increased area of cardiac dullness to the right. Sometimes a moderate œdema develops. In such cases the autopsy shows nothing as the cause of death but the changes in the lungs. The lungs are abnormally poor in air, small, and compressed, but in circumscribed portions, on the contrary, emphysematous and expanded. The right side of the heart in the great majority of cases is dilated and hypertrophied. There can scarcely be a doubt, therefore, that the cause of the onset of severe symptoms and the final cause of death is to be sought in the cardiac failure.

Finally, it is worthy of mention that there is a frequent form of mild atelectasis in the lower lobes, which occurs in very sick and bed-ridden patients who usually keep in one position—on the back—as in typhoid fever. On making such patients sit up we hear during the first inspirations exquisite crepitant râles over the lower lobes, which sometimes disappear after a few deep inspirations. Here we have to do with a mild atelectatic condition, with a temporary adhesion of the walls of the alveoli and smallest bronchi.

The **treatment** of atelectasis coincides in great measure with the treatment of the primary disease, and is therefore to be looked for in the corresponding chapters. The prophylaxis of atelectasis, by constant attention to the respiration, is of great practical importance. We should try to keep the patient from lying continually on his back, and we should make him take deep inspirations. The timely use of tepid baths, with shower-baths, is a special preventive of the development of atelectasis, and it may bring about a recovery when atelectasis is already present.

Tepid baths may also be used with care in the treatment of dyspnoea caused by

kyphoscoliosis. The condition of the heart, however, deserves especial attention (stimulants and digitalis). The reader is referred to the consideration of the general treatment of circulatory disturbances under Heart Disease. In other respects the symptomatic treatment by expectorants, etc., is the same as in other chronic pulmonary affections.

### CHAPTER III.

#### PULMONARY ŒDEMA.

**Etiology and General Pathology.**—We have in pulmonary œdema the exudation of a highly albuminous fluid, usually somewhat hæmorrhagic, not only into the interstitial tissue, but also into the alveoli themselves. The danger of the condition is easily understood from the high degree of dyspnœa which immediately ensues from it. In fact, pulmonary œdema is in many cases a terminal symptom, which comes on in all forms of acute and chronic disease. Many patients are said to die with the signs of pulmonary œdema, especially patients with heart disease, pulmonary and renal disease, and also with other affections of the most different kinds.

In rare cases pulmonary œdema is a transitory symptom. Repeated attacks of it may occur, especially in heart disease and chronic renal disease, and for a time at least, the patient recover from them.

Many erroneous notions formerly prevailed as to the particular cause of pulmonary œdema. The theory was especially wide-spread that arterial congestion in the lungs could excite an œdema, but through the experiments of Colinheim and his pupils we now know that pulmonary œdema is to be considered the result of stasis. It takes place when the outflow of venous blood in the lung meets an obstacle which can no longer be overcome by the mechanical force of the right ventricle. The obstacle which plays the most significant part here, and which may occur in all possible forms of disease—of course more readily in those mentioned above than in others—is the paralysis of the left ventricle. If the further progress of the blood is much hindered by this, the overfilling of the pulmonary circulation and a consequent pulmonary œdema will necessarily follow, in spite of the most vigorous action of the right ventricle. Every terminal pulmonary œdema depends upon this fact, that the left ventricle is paralyzed in its action sooner than the right.

Inflammatory pulmonary œdema must be distinguished from the pure œdema from stasis just described. It is found in the vicinity of portions of lung infiltrated with pneumonia, it is usually of limited extent, and therefore it is of subordinate importance as a cause of disturbances in respiration compared with the general œdema of stasis.

In very rare cases, as we have seen, an apparently primary acute pulmonary œdema, with a speedily fatal termination, develops in men who were before that apparently perfectly healthy, and the autopsy gives no further explanation of its origin. We probably have to do in these cases with the sudden failure of the left ventricle.

**Symptoms.**—Marked dyspnœa is the most striking symptom in pulmonary œdema. It is subordinate only when the patient is found in the death agony and is no longer fully conscious.

In pulmonary œdema the respiration is hurried, labored, and rattling. All the accessory muscles of respiration are called into play. The patient usually sits

upright in bed. We see on his lips and cheeks a gradually and constantly increasing cyanosis, and we often hear at a distance the moist râles in the larger bronchi.

On examination of the lungs, the percussion is essentially normal, if there is no other disease of the lungs. Sometimes the percussion-note is a little higher in pitch, and often it is slightly tympanitic. On auscultation, we hear everywhere many small and medium moist râles. If the patient can still expectorate, he raises a large amount of frothy, sero-hæmorrhagic sputum. The whole picture of the disease is so characteristic that the condition can scarcely be mistaken.

**Treatment.**—Since in most cases pulmonary oedema is not so much the cause as a symptom of approaching death, our remedies against it are apt to prove powerless, but it must always be our duty, at least in all cases that are not absolutely hopeless, to try to relieve the pulmonary circulation. From the pathogenesis of pulmonary oedema it follows that we must pay particular attention to the condition of the heart, especially of the left ventricle. Hence we should use energetic stimulants, especially subcutaneous injections of camphor or ether, every half hour or hour. Internally we give camphor, musk, wine, and strong *café noir*. Beside that, we apply strong irritants to the chest, such as large mustard plasters or hot sponges. Sometimes an actual improvement of the respiration, when it has already stopped, may be obtained by a bath with cold douching, where there is marked general cyanosis. If the patient is on the whole strong and well nourished, venesection is sometimes of manifest benefit. Emetics, however, accomplish little, and are even dangerous on account of the collapse which may readily come on after them. An energetic "derivation to the intestines," however, by senna, calomel, or enemata of vinegar, seems sometimes to be really of service. Acetate of lead in large doses, one or two grains (grm. 0.05–0.10), in powder, every hour, employed empirically by Traube, is deserving of trial.

In this way, especially in acute diseases like typhoid and pneumonia, we in fact sometimes succeed in averting the danger of pulmonary oedema by rapid and energetic action. In the cases of oedema occurring in incurable chronic diseases of the heart and kidneys, the remedies employed are of course unfortunately incapable of preventing death.

## CHAPTER IV.

### CATARRHAL PNEUMONIA.

(*Broncho-pneumonia. Lobular Pneumonia.*)

**Ætiology.**—Catarrhal pneumonia is not, like croupous pneumonia, a distinct and independent disease, but in the great majority of cases it is a secondary phenomenon, which may develop in the course of acute and chronic diseases of various kinds. It almost always follows bronchitis. The same process which produces catarrh of the bronchial mucous membrane, in its further course invades the bronchioles and the alveoli, and here leads to catarrhal pneumonia.

In every acute or chronic disease, of any severity, the conditions are favorable for the development of an inflammation in the bronchi, and subsequently in the pulmonary alveoli. Everywhere in the air-passages, as well as in the cavities of the mouth and pharynx, saliva, mucus, etc., readily collect if the patient is very ill. Expectoration is imperfect, and the constant dorsal decubitus favors the accumulation of secretion, especially in the lower lobes. The mouth and pharynx are harder to keep clean than under normal conditions. Fungi and bacteria collect in the secretion itself, as well as in the epithelium and particles of food which

are left in the mouth, and these excite and keep up processes of decomposition. The inflammatory agents, which are carried into the air-passages with the inspired air, find everywhere favorable conditions for settling and further development. From the upper portions they are drawn farther downward. From the larger bronchi the process invades the finer bronchi, and finally leads to catarrhal pneumonia. We must also bear in mind that many patients who are very ill have difficulty in swallowing. They get choked, and particles of food, with the germs of inflammation clinging to them, are carried into the air-passages. That which a healthy person could easily cough up again remains there, is decomposed, and gives rise to bronchitis and lobular pneumonia.

This is the explanation of the frequent development of lobular pneumonia in the course of diseases which are entirely dissimilar. We observe it especially in all patients with stupor, in severe typhoid, in meningitis, and also in cases of nervous disease, where coughing and deglutition are impaired, as a result of bulbar affections. In all such cases lobular pneumonia is to be considered a complication, and with reference to its origin deserves the name of inhalation pneumonia or deglutition pneumonia. We shall soon see that this form, under some circumstances, may pass into circumscribed gangrene.

Although the ætiological factors just described, which come into notice in the development of lobular pneumonia, have nothing to do with the nature of the primary disease as such, there are, on the other hand, certain infectious diseases which from the beginning are exclusively, or at least mainly, localized in the air-passages. Among these are measles, whooping-cough, and also, to a certain degree, diphtheria, small-pox, etc. In these diseases we very often see lobular pneumonia following bronchitis. In individual cases, of course, it is scarcely possible to decide how far the bronchitis is directly dependent upon the specific cause of the disease, or whether it is merely a complication such as might also occur in any other disease. Lobular pneumonia in diphtheria, and in severe small-pox, is probably for the most part a deglutition or an inhalation pneumonia, the occurrence of which in these diseases may be readily understood. In measles and whooping-cough, however, we may consider that the pneumonia is directly dependent upon the specific agents of the disease, although here, too, the other causes for the development of lobular pneumonia should be borne in mind.

The development of lobular pneumonia from bronchitis is most frequent, as we know, in children and old people. The frequency of catarrhal pneumonia in childhood depends in part upon the limited dimensions of the bronchi. Besides that, however, the diseases in which it is especially frequent—namely, measles and whooping-cough—are children's diseases. In old people its comparatively easy development is due to imperfect expectoration.

The mild cases of primary bronchitis scarcely ever lead to lobular pneumonia, but sometimes in children, and less often in adults, a severe febrile bronchitis may occasion the formation of pneumonic foci. Here, in Erlangen, the author has seen cases which can not be regarded otherwise than as primary catarrhal pneumonia. The inhalation of irritating chemicals may occasion lobular pneumonia as well as bronchitis.

**Pathological Anatomy.**—It is characteristic of catarrhal pneumonia that the inflammation is circumscribed, being limited to the territory of a small bronchus. Hence the name of "lobular" pneumonia, in distinction from or croupous lobar pneumonia. An atelectasis (*vide supra*) of the affected lobule, arising from the plugging of the bronchus leading to it, often, but not always, precedes the inflammation. The inflammatory process itself consists of the exudation of a scanty fluid, which does not coagulate, and of numerous pus-corpuscles (white blood-corpuscles)

into the lumen of the alveoli. The alveoli and smallest bronchi are completely filled by the pus-corpuscles. There are also more or less abundant red blood-corpuscles. The vessels of the alveolar walls are very hyperæmic. The alveolar epithelium is much swollen, and is often thrown off in quite large amounts, the "desquamative pneumonia." It is doubtful whether it also takes an active part in these changes by processes of division.

The inflamed lobules are readily apparent to the eye and the touch by their firm consistence, being devoid of air. Their color at first, from the blood contained in the inflamed part, is a dark red, but later it becomes more grayish. Their lobular boundary is usually easily recognized, but, by confluence of adjacent nodules, large portions of the lung, and even whole lobes, may become infiltrated throughout—generalized lobular pneumonia.

**Symptoms.**—The primary catarrhal pneumonia which not infrequently occurs in adults usually begins with the same phenomena as a severe attack of acute bronchitis. The patient feels prostrated, has cough, dyspnoea, and pain upon that side which is chiefly affected. The fever is not very high, say  $101^{\circ}$  to  $103^{\circ}$  ( $38.5^{\circ}$  to  $39.5^{\circ}$  C.), and it does not follow any regular course. The expectoration is simply catarrhal, not bloody as in croupous pneumonia. Upon physical examination are found moist râles, seldom marked bronchial breathing, and a dullness upon percussion which is usually only moderate, or else a tympanitic percussion-note over the diseased area. The illness may last two or three weeks, or even longer. There is never a crisis, the fever ending gradually by lysis.

Most of the cases of catarrhal pneumonia develop, as we have already said, secondarily in the course of other affections, hence the symptoms are frequently overshadowed by those of the other disease. There are often found at autopsy a few foci of lobular pneumonia in the lower lobes which gave rise to no clinical symptoms whatever.

In other cases, however, the development of extensive lobular pneumonia is of the greatest clinical significance. The disturbance of respiration, during the patient's life, forms the most striking symptom of the disease, and lobular pneumonia is shown at the autopsy to be the immediate cause of death. The largest part of the fatal cases of measles and whooping-cough, and no very small part of those of diphtheria, scarlet fever, typhoid, or small-pox, are due, in the last instance, to the disturbance of respiration dependent upon lobular pneumonia.

Since a diffuse bronchitis, extending into the finer bronchi, almost always precedes the development of lobular pneumonia, and since it may also give rise in itself to marked disturbance in respiration, there is no sharp boundary to be drawn clinically between diffuse capillary bronchitis and lobular pneumonia. Only the experience, a hundred times repeated, that every extensive capillary bronchitis readily leads to lobular pneumonia, permits us to suspect the latter, with considerable certainty, even if there is no direct clinical evidence of it.

The type of lobular pneumonia seen in childhood is the most characteristic and the most important clinically. It is observed in measles and whooping-cough, and also in weak, atrophic, and rachitic children. The increased frequency of respiration is most striking. The breathing is superficial, but labored, as is shown by the contraction of the auxiliary muscles of inspiration and the play of the nostrils. We also notice inspiratory retraction of the lower lateral portions of the thorax as a result of the incomplete entrance of air. The number of respirations a minute increases in children to sixty or eighty, or even more. In most cases the child has a frequent and apparently painful cough. Expectoration is entirely absent in small children. When it is present it shows no characteristic peculiarities different from ordinary catarrhal sputum. The general condition is always

bad. The child is restless, apathetic, and more or less stupid. Its face is usually pale, but often quite cyanotic. The pulse is very rapid, and in small children may attain a frequency of 140 to 180 a minute. Fever is almost always present. It shows no typical course, it is now remitting and now intermitting, and toward evening it perhaps rises to  $104^{\circ}$  or  $105^{\circ}$  ( $39.5^{\circ}$ – $40.5^{\circ}$  C.). The occurrence of such a high rise in temperature is not without value in the diagnosis of catarrhal pneumonia. If in diffuse capillary bronchitis a high fever is present for some time, we may assume with considerable certainty that the formation of lobular nodules has already begun.

Physical examination furnishes direct evidence of the affection of the lungs, but its results are for the most part to be referred to the diffuse bronchitis and not to the lobular infiltration. Auscultation gives the most valuable signs. We hear over the lungs, in a greater or less extent, numerous small and medium moist râles, often quite high-pitched. From these signs, strictly interpreted, we can diagnose merely bronchitis, but we may suspect pneumonia with the greatest probability. With very confluent broncho-pneumonia auscultation sometimes gives bronchial breathing and bronchophony beside the râles.

It goes without saying that little lobular nodules, surrounded by normal lung-tissue containing air, give no special signs on percussion. With numerous nodules running into one another, the percussion-note is duller, and there is sometimes tympanitic resonance. The dullness is often first to be made out over a stripe extending along the vertebral column—the so-called “stripe-pneumonia.”

**Course and Termination.**—An attack of extensive lobular pneumonia is usually quite protracted. Even in favorable cases the disease rarely lasts less than two or three weeks, and it may persist much longer. The course of the disease is apt to be irregular, relapses succeeding improvement. The chief danger of the disease lies in this tendency to a protracted course, extending over weeks and months. Many children finally die, not of the lobular pneumonia itself, but from the general weakness and emaciation following the tedious febrile disease. We must remember, however, that complete recovery may sometimes take place quite late in the disease.

The “transition of catarrhal pneumonia to caseation and tuberculosis” is a clinical fact with which physicians have long been conversant. In fact, we often find true tubercular changes in the lungs of children who have died after a tedious illness, as a result of measles, whooping-cough, etc. There can, of course, be no real question, however, of an actual transition from one disease to the other. In such cases we have to do either with an acquired tubercular infection, which has found a favorable soil in an already diseased lung, or (what is probably more frequently the case) the disease of the lung has promoted the development of a previously existing tuberculosis. It is usually weak children, with a hereditary predisposition to tubercle, who succumb to tuberculosis as a result of the above-named diseases. The diagnosis of a developing tuberculosis is not always easy, since it is only rarely that marked phthisical changes—like dullness at the apex, cavities, etc., which can be made out by a physical examination—are found in the lungs. We can usually suspect tuberculosis only from the general conditions—emaciation, persistent hectic fever, hereditary predisposition, or some secondary tubercular disease like meningitis, etc.—especially as absolute proof, from the detection of tubercle bacilli in the sputum, is only rarely possible in children.

The transition of inflammatory lobular nodules to purulent foci (abscesses), or nodules of gangrene, which sometimes happens, especially in small-pox, depends upon the specific malignant property of the agents of inflammation which have entered the bronchi.

If the lobular nodules extend to the pleura, a secondary sero-fibrinous or even purulent pleurisy may develop.

**Treatment.**—Since we have already mentioned the proper treatment, in our description of the various diseases in which secondary pneumonia is especially prone to develop, we can now be brief. We have also laid repeated stress upon the possibility and the great practical importance of prophylaxis, which is self-evident from a just comprehension of the origin of lobular pneumonia. Besides keeping the cavities of the nose, the mouth, and the pharynx as clean as possible, tepid baths, with cool douching later, are the best means of preventing the development of lobular pneumonia, or of checking its further extension if possible. Cold packs are often used with advantage, but they are more disagreeable to many patients than baths. It is an advantage, which is indeed to be considered in the second rank in comparison with the improvement in respiration, that by both the bath and the pack the febrile temperature is at the same time reduced.

In the treatment of the lobular pneumonia of children a wet pack including the whole body is the best remedy. A sheet is dipped in water, wrung out, and wrapped around the whole of the patient except his head and arms. Outside of this is to be placed a dry woolen blanket or a layer of oiled muslin. The temperature of the water employed should be  $68^{\circ}$  to  $77^{\circ}$  ( $16^{\circ}$  to  $20^{\circ}$  R.). The higher the fever the colder should the water be, and the oftener, say every hour, must the pack be renewed. In milder cases and at night it may be allowed to remain for three or four hours. The beneficial influence of the pack is shown not only by the temperature, but still more by the respiration. If the breathing, despite this remedy, remains unsatisfactory, and the patient becomes more and more stupefied, the treatment must be changed to lukewarm baths of a temperature of  $77^{\circ}$  to  $86^{\circ}$  ( $20^{\circ}$  to  $24^{\circ}$  R.), with douchings of colder water. It is sometimes advisable in severe cases to add to the water employed for bathing or for the wet pack a few handfuls of mustard. The stimulation thus exerted upon the skin is quite marked.

Among external applications to the chest, beside mustard plasters and poultices, dry cups are to be mentioned, which often do very good service in strong, older children, and especially in adults. We never need to use local blood-lettings, however, in catarrhal pneumonia.

Of internal remedies, expectorants are most used. Chief among these are ipecac, senega, and benzoic acid. This last is particularly useful in the lobular pneumonia of children. In strong children the abundant collection of mucus in the bronchi may sometimes be relieved by the administration of an emetic. We should be cautious in the use of narcotics. Stimulants (camphor, wine) must be used in severe cases. Inhalations are quite valueless in lobular pneumonia, yet it is recommended to keep the air in the sick-chamber rather moist by hanging up wet towels, or by sprinkling with water. The room should also be as large and as well ventilated as possible. The general hygienic treatment is of the greatest importance. One of the most important duties, of which the physician must always be mindful, is to keep up the patient's strength by sufficient and proper food. When convalescence sets in, complete restoration to health may be furthered by a suitable residence in the country.

## CHAPTER V.

## CROUPOUS PNEUMONIA.

(Lung Fever. Lobar Pneumonia. Fibrinous Pneumonia. *Neuro-pneumonia*.)

CROUPOUS pneumonia is an acute febrile disease of the lungs, very sharply defined both anatomically and clinically. It is one of the most important and most common of the severe acute diseases. It is generally known among the laity by the name of "lung fever." Since secondary pneumonia may develop in the course of various other diseases, like typhoid, small-pox, or diphtheria, and may anatomically have all the signs of croupous pneumonia, but etiologically be quite distinct from it, we speak of this pneumonia as primary, genuine pneumonia, in opposition to the other forms. The physical signs and the disturbances of respiration are of course the same in primary pneumonia as in secondary. The whole typical picture of the disease, which is so striking, is seen, however, only in genuine croupous pneumonia, of which we will make exclusive mention in what follows.

**Ætiology.**—The majority of pathologists have now become convinced, from a series of clinical observations, that the cause of pneumonia is to be sought in an infectious agent which enters the lungs and there gives rise to the development of an inflammatory process. This conception of croupous pneumonia as an acute infectious disease, with which alone all the pathological appearances readily coincide, has been more and more verified by all the recent investigations. The precise germ of the disease has not yet, however, been fully determined. Friedländer, indeed, has almost invariably found in the pneumonic lung a special kind of micrococcus, or, to speak more correctly, bacillus, which, singly or in larger numbers, is inclosed in a characteristic shell or capsule—"capsule coccus"—and on cultivation shows a peculiar "nail-like" growth in the culture gelatine; but since quite similar cocci are also found under other conditions, there is no definite proof at present that they are really the pathogenic agents in pneumonia, particularly as the results of experiments upon animals have not been unambiguous.

[Friedländer himself has now agreed that the capsule is simply accidental, probably due to imperfect staining or decolorization. Talamon has produced pneumonia in animals by the injection of the ovoid coccus in pure culture, but has obtained also a similar result with round cocci. Thus the question of the coccus of pneumonia is still undetermined.]

A. Fränkel has lately obtained by means of pure cultivation from the lungs in pneumonia a lancet-shaped diplococcus, or, more correctly, bacillus, to which he ascribes an ætiological significance. This bacillus appears to be identical with that sometimes seen in the saliva, even in that of healthy persons, and it is the cause of the so-called "sputum septicæmia" which can be artificially produced in animals, particularly in rabbits. Fränkel's statements have been confirmed by Weichselbaum, so that the very frequent occurrence of Fränkel's bacillus in lungs affected with pneumonia is indubitable, but an absolute proof that these bacilli are the genuine cause of croupous pneumonia has not yet been furnished. Supposing the infectious nature of pneumonia to be certain, all the other alleged causes may of course be regarded as at most "predisposing causes." The old opinion, which is yet current, that pneumonia is due to catching cold, is to be received with great limitations, for croupous pneumonia is very frequently seen independently of any such influence. In a good many cases it will be found that an exposure to cold immediately preceded the commencement of the disease; but in these instances the cold is probably to be regarded merely as that

circumstance which promoted the occurrence of the infection, possibly because of the resultant injury to the bronchial and pulmonary epithelium. This explains the fact that pneumonia is especially frequent in certain classes, for instance, among day-laborers and soldiers. With regard to the so-called "traumatic pneumonia," the state of the case is similar to that of pneumonia due to cold. Patients from the classes who work hard physically sometimes assert that they were taken ill as a result of heavy lifting or of a blow on the chest, but in such cases the subsequent stitch in the side was probably not the result of the injury, but a symptom of the disease which had previously begun to develop.

It is a noteworthy fact in favor of our conception of pneumonia as an acute infectious disease that it may be endemic; which sometimes, though rarely, seems to be quite certain. Extensive epidemics of pneumonia, usually of quite a malignant character, have been repeatedly observed in single buildings, especially in barracks or prisons, as well as in tenement houses and other localities.

Pneumonia does not show a decided epidemic character. In a large population sporadic cases occur at any season, but, on the other hand, we may notice a striking increase of pneumonia at many times. Most attacks occur in the winter or spring months, without any necessary relation, however, between the frequency of pneumonia and the occurrence of especially bad, wet, or cold weather.

Individual predisposition plays an unmistakable part in the disease, as we must suppose that it does in all infectious diseases. Like facial erysipelas and acute articular rheumatism, pneumonia is one of those diseases which is prone to attack the same individual several times. There are persons who have had acute pneumonia four or five or even more times in their lives.

We can not affirm with certainty that the liability to pneumonia is due to a special bodily constitution. The strongest and most robust often fall ill with it, and, on the other hand, weak and delicate people, with a tendency to phthisis, are frequently attacked. Drunkards seem to have a special predisposition to the disease, but of course it is exceedingly hard to give any definite statistics upon this point.

Pneumonia occurs at any time of life, most frequently in youth or middle age; but it is by no means rare in early childhood, and also in more advanced years up to sixty or seventy. In general it is observed rather more often in men than in women.

[Defective house drainage seems to be a predisposing cause of pneumonia in some cases. A careful inspection of the local sanitary conditions is desirable, especially where more than one case occurs in a house.]

**Pathological Anatomy.**—The anatomical process in croupous pneumonia consists in the formation of a hæmorrhagic, coagulable "fibrinous" or "croupous" exudation into the pulmonary alveoli and the smallest bronchi. The development of the exudation usually extends over one or more lobes to their whole extent, and, as the alveoli and fine bronchi are completely filled by the tough exudation, the spongy lung, filled with air, is changed to a firm tissue, devoid of air, except as it is penetrated by the large bronchi.

Since Laennec's day we distinguish three stages in the development of the process. In the first stage (stage of inflammatory engorgement, *engouement*) the lung is very hyperæmic, dark red, and the air contained in it is even now much diminished, but not entirely absent. The alveoli are filled with an abundant exudation, already hæmorrhagic, but still fluid and not coagulated.

In the second stage (stage of red hepatization) the coagulation of the exudation is complete, and the lung has become throughout of the consistency of liver. The hepatized lung shows a somewhat increased volume, and is strikingly hard. The surface of the section has a red and manifestly granular appearance, which is due

to the projection of the numerous little fibrinous plugs situated in the alveoli. With the knife we can scrape off a tenacious, creamy, grayish-red fluid from the surface of the section. In the small bronchi, divided by the section of the lung, we find characteristic tubular bronchial casts.

In the third stage (stage of yellow or gray hepatization), which gradually develops from the second, the red color of the surface of the section changes to a yellowish gray, while the contents of the exudation grow poorer in red but richer in white blood-corpuscles. The consistency of the lung is still dense but more boggy. The fluid scraped from the surface of the section is more abundant, milky, and more like pus. We also speak, therefore, of a "stage of purulent infiltration."

The recovery from the process begins as the exudation becomes fluid. The fluid is in part absorbed and in part coughed up.

It is not necessary for every pneumonia to go through all three stages completely. In mild cases the process may stop sooner and go on to recovery.

Concerning the finer histological processes in croupous pneumonia, the primary change is probably to be found in the injury and partial destruction of the epithelium in the alveoli and smallest bronchi, produced by inflammation due to the specific causes of the disease. As in every croupous inflammation of a mucous membrane (see the chapter on diphtheria), a coagulable exudation is formed on the surface of the alveoli and smaller bronchi after the destruction of the epithelium. With the microscope we see the fibrinous net-work of the exudation filling the alveoli. Between its meshes lie numerous red blood-corpuscles—red hepatization. Where there is any of the alveolar epithelium left, we often notice active proliferation—increase and growth of cells. Later on the white blood-corpuscles increase, migrating from the vessels into the exudation—yellow hepatization. The red blood-corpuscles are dissolved unless they are removed by expectoration. The fibrinous exudation is also gradually dissolved as the result of chemical changes not yet clearly understood (peptonization of the albuminous substances?), and is absorbed like the cells. The regeneration of the missing epithelium comes from the epithelium that has remained intact, and with that follows a gradual and complete *restitutio ad integrum*.

The whole process is comparatively brief, usually running its course in a week or ten days. The most frequent termination is in complete recovery. The other methods of termination, as well as the complications in other organs, will be spoken of in connection with the clinical symptoms. We may here mention simply that the pleura over the affected portion of the lung takes part in the inflammation, without exception, as soon as the disease reaches the periphery, and a fibrinous pleurisy, which is not very intense, may then be recognized; hence the former use of the terms "pleuro-pneumonia" and "peripneumonia."

Croupous pneumonia usually spreads rapidly over a great part of the lung. It is very often quite sharply limited to a single lobe—"lobar pneumonia"—so that the septum of connective tissue between two lobes also forms a strict boundary between pneumonic infiltration and healthy lung tissue; but this boundary is by no means insurmountable, and quite frequently several lobes are wholly or in part attacked by pneumonia. According to all statistics, the lower lobes are more frequently affected than the upper. Isolated disease of the right middle lobe may occur, but it is much rarer than pneumonia of the upper lobes. Of the two lungs, the right is attacked with decidedly greater frequency than the left. We have ourselves seen, in 244 cases, 137 on the right, 86 on the left, and 21 in which both lungs were attacked to a great extent. Simultaneous affection of the lower lobe on one side and the upper lobe on the other—quite a rare occurrence—is termed "crossed pneumonia."

**General Course of the Disease.**—In spite of the numerous modifications which the course of pneumonia may undergo in individual instances, we can still call pneumonia a typical disease, considering the great majority of cases. The subjective and objective symptoms dependent upon the local affection of the lung usually, but not always, take the chief place among the clinical appearances. In this, pneumonia differs from many other infectious diseases, like typhoid, in which the local affection is subordinated to the general infection.

Pneumonia usually begins quite suddenly. In the majority of cases it starts with a pronounced chill of half an hour to an hour's duration, or at least with a marked and prolonged chilliness. The initial chill may attack the patient while in the best of health. It comes on in the day-time, in the evening, or even in the middle of the night, after a previously quiet sleep. At the same time the patient almost always feels as if a severe illness were beginning.

In other and somewhat rarer cases the beginning of pneumonia is more gradual. A prodromal stage of a few days, or even longer, precedes the severe illness. The symptoms are either of quite a general and indefinite nature, consisting of malaise, dullness, loss of appetite, and headache, or the signs of a pulmonary affection follow the prodromal symptoms more closely. The patient always complains, for some days or weeks before the special severe illness, of cough, some pain in the chest, or slight trouble with breathing. We can not usually be sure whether these prodromata belong to pneumonia or not: a pre-existing simple bronchitis may often furnish the most favorable soil for the development of pneumonia.

In the cases where the disease begins more slowly, the onset of severe symptoms is sometimes marked distinctly by a chill or by sudden thoracic distress. In other cases the patient grows worse gradually, without any abrupt change.

The subjective symptoms in the chest begin, as a rule, a short time after the onset of the disease, on the first day or only a little later. The patient feels on every deep inspiration a stabbing pain in one side. The breathing is shallow, accelerated, and often somewhat irregular. Later on, in severe cases, there is very marked dyspnoea and rapidity of respiration. There is usually an irritating cough from the beginning of the disease. The cough is painful, and hence short, half suppressed, and quite frequent and troublesome. From the second day the expectoration may assume its characteristic viscid, rusty, hæmorrhagic appearance. Physical examination gives on percussion and auscultation the signs to be described more fully below. These are rarely to be found on the first day, but more frequently on the second, and sometimes not till later.

Among the appearances in other organs we may mention, as the most important in diagnosis, the very frequent occurrence of herpes on the lips or on the alæ of the nose. In severe cases there are sometimes marked symptoms on the part of the nervous system—headache, sleeplessness, and delirium. The appetite is usually completely lost. Vomiting is not infrequent, especially in the beginning of the disease. The bowels are usually constipated, but diarrhoea may sometimes be present.

Pneumonia is almost always associated with high fever. The typical character of the disease may be best demonstrated by the behavior of the temperature curve. A corresponding increase in the frequency of the pulse is seen with the increase of the temperature.

The course varies greatly according to the previous individual circumstances, the severity of the disease, and the existence of complications. In the majority of cases, after a comparatively short duration, the disease takes a favorable turn. The beginning of improvement is often sudden, like the onset of the disease. After the symptoms have lasted for some five to seven days, or in rarer cases a

shorter or a longer time, at a constant height or with increasing intensity, there occurs in the regular course of the disease a critical decline of the fever, frequently associated with quite a copious perspiration, and with that a very rapid improvement of all the other symptoms. In a short time complete recovery follows.

In other cases, however, the course is not so favorable. The disease may have a fatal termination. In a third small class of cases the disease finally takes a protracted course, which is usually due to the occurrence of abnormal sequelæ in the lungs.

#### DESCRIPTION OF SINGLE SYMPTOMS AND COMPLICATIONS.

**1. Symptoms on the Part of the Lungs.**—The chief subjective symptom in pneumonic patients is the characteristic painful feeling in the affected side—the "stitch in the side." This probably always has its origin in the dry pleurisy which accompanies the pneumonia. It is therefore absent in the cases of central pneumonia (*vide infra*). In pneumonia of the lower and right middle lobes the pain is usually more severe than in pneumonia of the upper lobes. One result of the stitch in the side is the difficulty, or even the impossibility, of deep inspiration. Hence the patient's dyspnoea is considerably increased, and this explains the incongruity between the shortness of breath and the relatively slight extent of the pneumonia in many cases. The subjective feeling of difficulty of breathing is present in the majority of cases, and it may become most distressing.

Cough is one of the most constant symptoms in pneumonia, and is usually very painful; hence the patient often tries to suppress it. Expectoration is apt to be very difficult at the onset of the disease, from the viscosity and scanty amount of the sputum; hence very severe and distressing paroxysms of coughing are sometimes observed. The cause of the cough is probably not to be found in the affection of the alveoli, but in the co-existing bronchitis. The irritation of the pleura may also set up a reflex cough. In rare cases cough is entirely absent in pneumonia. Except in the cases of limited or late localization (*vide infra*), we observe this absence of cough chiefly in the pneumonia of old or very weak people, and also, what is of practical importance, in the drunkard's pneumonia associated with delirium tremens.

The pneumonic expectoration is so characteristic that we can often make the diagnosis of croupous pneumonia from this alone. It consists of a very tough mucus, which sticks fast to the bottom of the vessel, and is mixed with blood, and therefore has a more or less intense red or yellow hæmorrhagic color. In individual cases there are numerous gradations. We usually call the pneumonic sputum "rusty," or "brick-red," or of a "prune-juice color," etc. Sometimes it has only a slight reddish or yellowish tint, and sometimes it consists almost entirely of blood. In some cases it assumes a peculiar grass-green color, which is due to a change in the blood coloring-matter, or to a mixture with bile pigment in "bilious pneumonia."

The red color of the sputum, as microscopic examination shows, is due to numerous red blood-corpuscles, still well preserved, mixed with it. They are, however, in part dissolved, and hence cause the uniform red color of the sputum. Separate spots containing much blood are often seen in it. Besides the red blood-corpuscles, the microscope shows numerous partly swollen or fatty degenerated pus-corpuscles. We also see long threads of mucus; sometimes large, round, pigmented cells (alveolar epithelium?); and finally, in rare cases, ciliated epithelium and crystals of hæmatoidin. Micrococci always, and capsule-cocci frequently (*vide supra*), are to be found in stained preparations, but these have at present no diagnostic value, since nothing certain is known as yet as to their significance.

We have still to mention the bronchial casts as important constituents of pneumonic sputum. Since they are usually rolled up together, we may not find them except by spreading out the sputum in water. They consist of the most beautiful casts of the small bronchi, with many dichotomous divisions, and are a product of the croupous inflammation extending into the bronchi. The casts of the smallest bronchi are sometimes found in the form of "spirals," like those in asthmatic bronchitis (see page 169).

The amount of the pneumonic sputum is, as a rule, not very considerable, but it differs a good deal in different cases. The chemical examination of the sputum has so far given no remarkable results. The amount of common salt contained in it is quite considerable.

In many cases the pneumonic expectoration is absent. Sometimes it is very tough and slimy, but without any admixture of blood; in other cases the sputum is simply catarrhal, when present at all, and then, of course, it comes not from the parts infiltrated with pneumonia, but from the catarrh of the larger bronchi. We often find simple catarrhal sputum, too, beside the characteristic pneumonic sputum.

The pneumonic sputum sometimes is seen in the first or second day of pneumonia, but perhaps not till later. With the beginning of resolution it gradually loses its characteristic appearance. The expectoration then becomes less tenacious and simply muco-purulent, and finally disappears entirely.

**Physical Examination.**—Inspection shows no especial anomaly in the general contour of the thorax. A marked bulging of the affected side occurs only when there is also abundant effusion into the pleural cavity. The action of the thorax in respiration is very important. With a limited pneumonia we often notice a very marked delay and limitation of motion of the affected side on inspiration. This is due in part to the pain in the side, which comes on with every deep inspiration, and also, in extensive pneumonia, of course, to the physical conditions resulting from the anatomical changes. The unaffected portions of the lung act all the more forcibly.

The acceleration of respiration is very striking, its frequency increasing to thirty or forty, or even more, a minute. We have repeatedly counted sixty respirations in adults, even in cases that finally resulted favorably. The breathing is shallow, but yet in all severe cases very labored. We see the inspiratory contraction of the sterno-cleido-mastoids and scaleni in the neck, and often in the face a marked dilatation of the nostrils on inspiration. The patient usually reclines in bed with the upper half of the body raised. The cheeks and lips are cyanotic. The pale parts about the corners of the mouth are often sharply contrasted with the circumscribed bluish-red coloring of the cheeks.

The results of percussion are directly dependent upon the changed physical condition in the lung, due to the anatomical processes. In the beginning of pneumonia, so long as the total amount of air in the lung remains unaltered, the percussion-note remains clear, but when the elasticity and tension of the tissue in the diseased portion of the lung diminish, the resonance often becomes quite tympanitic. With increased exudation into the alveoli and smallest bronchi the amount of air in the lung constantly grows less, and therefore the percussion resonance becomes very dull, but it usually retains its tympanitic timbre. Since the pneumonic lung is only rarely absolutely deprived of air—for a certain amount is always left in the larger bronchi—the percussion resonance seldom becomes so completely dull—"flat"—as it does, for example, with a large pleuritic effusion. As soon as the absorption of the exudation begins, the volume of air in the lung increases, and the percussion-note becomes clearer, and remains for some time still markedly tympanitic, until the lung has regained its normal tension and elas-

ticity. We have also to note that the intensity of the dullness in croupous pneumonia is sometimes subject to quite marked variations, since the secretion retained in the bronchi is at one time abundant and at another, after expectoration, scanty.

The extent of the dullness or of the tympanitic resonance is naturally dependent upon the extent of the anatomical process. Small and central infiltrations may entirely escape detection by percussion.

Auscultation is of greater importance than percussion in the detection of a beginning or limited pneumonic infiltration. The auscultatory signs depend in part upon the presence of the pneumonic exudation and in part upon the change of the lung into a firm tissue containing air only in the larger bronchi. In the beginning of the disease we hear over the affected portions large or small râles, and very often, too, the characteristic crepitant râle on inspiration discovered by Laennec. This arises because the walls of the alveoli and smallest bronchi, which are cemented together, are torn apart at each inspiration. The crepitation, however, is neither pathognomonic of pneumonia, nor is it heard in every case of pneumonia. With increasing infiltration, bronchial breathing replaces the vesicular. The bronchial breathing in pneumonia is, as a rule, very loud and sharp, and sounds close to the ear. Beside this, we may detect more or less numerous sonorous rhonchi. We may hear a pure, loud bronchial breathing when there is marked infiltration, without any adventitious sounds. With the beginning of the "resolution of pneumonia"—that is, as soon as the exudation becomes more fluid—abundant, loud, moist râles occur, which are usually rather large, and they more or less obscure the bronchial breathing. At this time we frequently hear the characteristic crepitant râle again—*crepitatio redux*. The râles gradually disappear, the respiratory murmur loses its bronchial character, becomes harsh and indefinite, and finally is normally vesicular once more.

We often hear a few rhonchi over the unaffected portions of the lungs, but the respiratory murmur is completely normal over them.

The auscultatory signs just described undergo an important change if the larger bronchi leading to the affected portion of the lung are completely plugged by the secretion, as they are quite liable to be. The respiratory murmur may then almost entirely disappear, and we hear, perhaps, only here and there a few obscure râles. Since such a plugging may be very transitory, we understand why in one day, over the same portion of the lung, we hear first loud bronchial breathing and râles, and then quite obscure and diminished breathing.

Wherever there is bronchial breathing, we hear marked bronchophony. The vocal fremitus persists or is somewhat increased over a pneumonic lung so long as the large bronchi are open, but when they become plugged, the vocal fremitus is weakened or wholly absent.

We have yet to add a few remarks about the parts of the lung in which we may expect first to perceive the physical signs of pneumonia, especially the auscultatory signs.

In the first place, we should never neglect to examine carefully the lateral portions of the thorax and the axillary region when we suspect a developing pneumonia. We often find the first râles here in pneumonia of the lower lobes. The first signs of infiltration may be found in the posterior middle portion of the thorax, and extend downward from this point. Pneumonia of the upper lobes begins just as frequently behind in the apices as in front in the infra-clavicular fossae. Isolated pneumonia of the right middle lobe also occurs, to be made out in front, on the right, between the fourth and sixth ribs.

Few general statements can be made about the nature or the rapidity of the extension of pneumonia, since in these respects the greatest differences are observed. The infiltration may remain confined to a small portion of the lung,

and again it may spread over a whole lobe or more in a short time, even in one or two days. We call the pneumonia, whose constant extension by contiguity we can follow from day to day, wandering pneumonia (*pneumonia migrans*), or, from a purely superficial resemblance, which has given rise to many wrong ideas, "erysipelatous pneumonia." In these cases all the signs of resolution are present in the parts first attacked, while the parts affected later are found still at the height of the disease, or in the beginning of infiltration; but we may also find in the autopsies of wandering pneumonia the parts of the lung affected later in a more advanced stage (gray hepatization) than the parts first attacked, which are still in the stage of red hepatization. Wandering pneumonia is almost always severe and quite protracted.

Pneumonia in rare cases progresses by leaps. Such cases have been termed erratic pneumonia.

**2. Symptoms on the Part of the Pleura.**—As we have already mentioned, every pneumonia which reaches the periphery of the lung is associated with a fibrinous pleurisy, but in many cases this causes no objective symptoms. The stitch in the side in pneumonia, however, is due to the affection of the pleura. In other cases the dry pleurisy is marked by a distinctly audible, and often a very loud, pleuritic friction-sound, and a rub, which may sometimes be felt by laying the hand on the chest wall. We rarely hear the pleuritic friction sound in the beginning of pneumonia, but more frequently in the later stages, and perhaps not till many days after the crisis has taken place.

The cases in which pleurisy with effusion develops as a sequel to pneumonia, which may occur quite early, are more important. We usually have to do with a serous effusion, but in rare cases purulent pleurisy also comes on after pneumonia. Purulent effusions of this kind have been repeatedly found to contain the above-described lancet-shaped pneumonia coccus. In one case, which ended fatally, we saw a hæmorrhagic pleurisy, leading to an abundant effusion of blood into the pleural cavity.

The diagnosis of pleurisy with effusion, complicating pneumonia, is seldom difficult. The percussion resonance is duller than we find it in pure pneumonia (*vide supra*). The respiratory murmur and the vocal fremitus are constantly diminished and finally entirely absent. The symptoms of pressure on the neighboring organs and cavities, the heart, the liver, and the semilunar space (see page 260), are especially important because they are most unequivocal. An exploratory puncture with a Pravaz's [hypodermic] syringe, that has been carefully cleansed and disinfected, gives a very certain and safe method of recognizing pleurisy in doubtful cases.

A moderate degree of pleurisy may somewhat delay the course of the disease, but it has no special significance. Large effusions, however, may decidedly increase the difficulty in respiration. Otherwise the pneumonia may recover, leaving the pleuritic effusion quite undisturbed. In pneumonia of an upper lobe, too, the pleurisy may develop below and lead to an effusion there, while the lower lobe itself remains quite free from pneumonia.

**3. Circulatory Apparatus.**—The pulse is accelerated from the beginning of the disease. In cases of moderate severity its frequency reaches 100 or 120, and, in very severe cases, a still higher rate up to 140 or 160 is seen, and is always a dangerous symptom. This high rate of the pulse does not have as bad a significance in children as it does in adults. The consideration of the quality of the pulse is important. Smallness, weakness, and irregularity of the pulse are of bad omen as symptoms of the onset of cardiac weakness. The attacks of collapse, which sometimes come on quite suddenly in severe cases of pneumonia as in other acute diseases, are especially dangerous. They consist of sudden attacks of weak-

ness of the heart with a very small and frequent pulse. The temperature sinks to subnormal,  $95^{\circ}$  to  $93^{\circ}$  ( $35^{\circ}$ – $34^{\circ}$  C.). The peripheral parts, the nose and extremities, become cool, pale, and somewhat cyanotic. The general weakness is extremely marked. The collapse may be recovered from, especially with timely assistance, but patients may die in it.

The pericarditis that sometimes accompanies a fibrinous or sero-fibrinous exudation is one of the most important anatomical changes in the heart. This can always be explained by a direct conduction of the inflammatory process from the neighboring pleura, and is therefore somewhat more frequent in left-sided pneumonia than in right. It is a complication to be borne in mind. Its diagnosis is seldom difficult if we make a careful physical examination of the heart, but with very severe and extensive symptoms in the lungs a complicating pericarditis may be overlooked.

A slight fresh endocarditis is sometimes found on autopsy, but it has no clinical significance. Diseases of the cardiac muscle, especially fatty and parenchymatous degeneration, may be discovered *post mortem*, but they are by no means frequent. In very weak people, drunkards, etc., who die of pneumonia, we sometimes, indeed, find the heart remarkably flabby, with the right ventricle dilated, but in many cases of pneumonia we find the muscle of the heart at the autopsy perfectly normal. A constant relation between the finer histological changes in the cardiac muscle and the condition of the heart's action during life is, at any rate, not proved.

**4. Digestive Apparatus.**—In severe cases of pneumonia the tongue is dry, coated, and quite like the tongue in typhoid. The appetite is also almost wholly lost from the beginning. Vomiting is not infrequent, especially in the beginning of pneumonia, and it also occurs later. It is observed with especial frequency in the pneumonia of children. Severe symptoms on the part of the intestinal canal are rare. The bowels are ordinarily somewhat constipated, but quite severe diarrhoea is also observed.

The complication of pneumonia with jaundice has a certain significance, but its causes are not always very clear. It is sometimes due to an accompanying catarrh of the duodenum. In other cases the veins of the liver, dilated from stasis, may exert a pressure on the bile-ducts. Slight jaundice has no special significance, and is frequent, even in mild cases; a marked jaundice, however, is seen only in severe cases, especially in drunkards' pneumonia. We call such cases, associated with jaundice, "bilious pneumonia." They have often other severe gastro-intestinal symptoms, like vomiting, diarrhoea, and meteorism, and severe nervous symptoms, like stupor and delirium.

The liver sometimes shows the signs of passive congestion. The spleen is moderately enlarged, especially in severe cases—acute splenic tumor—as in other acute infectious diseases.

**5. Kidneys and Urine.**—The infectious character of pneumonia is also shown by the occurrence of a genuine acute nephritis, which is not especially common, but which still has been repeatedly observed. It begins most frequently on the third to the sixth day of the disease. It is recognized by the presence of albumen, casts, and blood in the urine. The nephritis usually gets perfectly well, but we have once seen it pass into the chronic form. The slight albuminuria which is found in severe pneumonia is, in our opinion, also due to a mild disease of the kidneys, and not to the fever as such (see the section on diseases of the kidney, pages 825 and 837).

Great weight was formerly laid upon the diminution of the chlorides in the urine in pneumonia. In fact, the precipitate of chloride of silver, when we put a drop of solution of nitrate of silver into the urine, may be very slight or entirely

absent. The chief cause of this diminution of the chlorides is the small amount of nourishment taken by the patient, but we must also bear in mind the large amount of chloride of sodium contained in the pneumonic exudation.

Great significance was also formerly laid upon the abundant sediment of uric acid (*sedimentum lateritium*—brick-dust sediment) which is often noticed on the day of the crisis. This is in part due to a real increase in uric acid, but in greater part to the fact that the conditions for the deposition of the sediment are especially favorable on that day. The urine is scanty in amount from the abundant perspiration, and is concentrated and relatively very acid. The uric acid contained in it can therefore readily be precipitated in the form of a sediment.

Pneumonia, in common with most of the other acute febrile diseases, is attended with an increased secretion of urea during the disease.

6. **Nervous System.**—As in every severe febrile disease, nervous symptoms of a mild type are very rarely absent in any case of pneumonia. Among the nervous symptoms are the general weakness and dullness, and especially the headache, which is often very intense, and is usually increased by coughing. The onset of more severe cerebral symptoms, especially delirium, is of great importance. We see this chiefly in individuals who have a peculiar predisposition to delirium, and particularly in drunkards. Delirium gives the drunkard's pneumonia (*vide infra*) its characteristic stamp.

While no anatomical basis has as yet been discovered for the above-named symptoms, nor for the worst form of delirium in drunkards, there is an anatomical disease of the brain which is, to be sure, a rare complication of pneumonia, but which yet is undoubtedly related to it: this is purulent meningitis. This complication has been repeatedly observed, especially at times when an epidemic of cerebro-spinal meningitis was prevailing, and also at other times. It is usually hard to make the diagnosis of a complicating meningitis, since its appearances are hidden under the other severe symptoms. The chief points for diagnosis are intense headache, rigidity of the neck, and a stupor increasing to deep coma. In many cases these symptoms are very slightly developed. The termination of meningitis is probably always fatal.

7. **Skin.**—The frequent appearance of herpes in the course of pneumonia is characteristic, and is sometimes of diagnostic importance. It appears from the second to the fourth day of the disease, or sometimes later. Its ordinary seat is on the lips, especially at the corners of the mouth, also on the alæ of the nose, and more rarely on the cheeks or the ear (*herpes labialis, nasalis*, etc.). It has been seen only very rarely on other portions of the body beside the face, for example on the forearm and the buttock, and in some cases on the mucous membrane of the tongue. We once saw two eruptions of herpes separated by an interval of several days. In repeated instances, under our own observation, herpes labialis, with a fresh rise of temperature, appeared some days after the crisis had taken place. The especial cause of the development of herpes in pneumonia is unknown to us. It is connected, at all events, with the infectious nature of the disease, and it is accordingly quite analogous to the occurrence of herpes in intermittent and recurrent fever, epidemic meningitis, etc. Other affections of the skin are of rare occurrence. We have seen urticaria in some cases. The jaundice occurring in pneumonia has already been described.

8. **Course of the Fever** (see Figs. 23 and 24).—Pneumonia is, almost without exception, accompanied by a more or less high fever with a very typical course. In the beginning of the fever the temperature rises very rapidly to a high point. Even during the initial chill the bodily heat increases from normal to about 104° (40° C.) and over. There are at present no observations to show whether,

in the cases of pneumonia that begin gradually, there is also a gradual increase of the fever. During the course of the disease the fever shows on the whole a continuous or remitting character, but there is with this a decided tendency to single deep falls of temperature. Since these at first may easily be taken for the actual occurrence of crises, although later they are proved by the renewed rise in temperature to be a mere temporary decline in the bodily heat, they are termed pseudo-crises. Pseudo-crises are usually seen in the first days of the disease, but in some cases they appear later. They may be repeated once or oftener, so that then the fever has a decidedly intermitting course. These intermitting pneumonias, so called from the course of the fever, have nothing at all to do with malaria, which fact must be especially noted because of the frequency of erroneous statements.

The fever may be decidedly high in pneumonia, often reaching  $104^{\circ}$  or  $106^{\circ}$  ( $40^{\circ}$ – $41^{\circ}$  C.). The highest temperature observed by us was  $107.8^{\circ}$  ( $42.1^{\circ}$  C.). In general there is a correspondence between the height of the fever and the severity

FIG. 24.—Example of the temperature curve in "intermitting" pneumonia. (Personal observation.)

of the case, but sometimes the most severe and even fatal cases run their course with a comparatively low fever, varying between  $101^{\circ}$  and  $103^{\circ}$  ( $38.5^{\circ}$ – $39.5^{\circ}$  C.). We expect the greatest increase in temperature in the first days of the disease. We have certainly not seen such a special increase immediately before the crisis—the so-called *perturbatio critica*—as many statements would lead us to expect. We have seen a gradual decline in temperature quite frequently in the closing days in fatal cases, but the opposite condition also obtains. A marked rise before death is

FIG. 23.—Example of the temperature curve in croupous pneumonia. (Personal observation.)

not peculiar to pneumonia, but it does occur when there is a complicating meningitis.

The decline of the fever is the most characteristic portion of the pneumonia curve. The fall in temperature usually comes on in the form of a decided crisis.

During the night there is generally a sinking of the temperature with a more or less abundant perspiration, in which as a rule the temperature may reach a subnormal point—96° to 95° (36°–35° C.). The critical decline is often broken by new and slight elevations of temperature, so that on the morning of the next day there may be a definite increase of fever, the so-called protracted crisis. Only in a comparatively small number of cases does the fever end by lysis, in which the temperature goes down like steps. The duration of lysis is seldom more than three or four days at most. A decline of temperature by lysis is most frequent in severe and protracted cases, in so-called typhoid pneumonia (*vide infra*), or in pneumonia migrans.

Although the pathological process in the lungs by no means ends with the crisis, we usually consider the day of the crisis as the last day of the disease. The pneumonia makes no advance after that, but resolution and absorption of the exudation and the return of the patient's strength still take time. Hippocrates knew when the time of the crisis occurs, and that the odd days, especially the fifth and the seventh, have a special significance in regard to it. In an infectious disease that has a typical course there can be nothing strange in the fact that the cessation of fever, to a certain degree, is associated with a definite period of time; but Hippocrates's rule has frequent exceptions. The crisis sometimes occurs on the ninth, the twelfth, or the thirteenth day, and even later, and, on the other hand, there are quite short pneumonias of but one or two days' duration.

In the days following the crisis the temperature, which, as we have said, falls to subnormal, regains its normal height. The pulse, which usually sinks to fifty or sixty during the crisis, when it often shows a slight irregularity, reaches its normal frequency again in a few days. We are quite apt to see, in the days immediately following the crisis, a slight increase of temperature again, 100° to 102° at most (38°–39° C.), but this has no special significance.

The general revolution which the whole condition of the patient undergoes after the crisis is often astonishing. The rapid decline in the respiratory symptoms is especially striking. The return of the affected portion of the lung to normal follows in quite a short time. The expectoration is more abundant but less viscid. It loses its bloody character and is simply catarrhal. In cases which run their course regularly, the signs in the lung on auscultation and percussion become normal again in about five to eight days after the crisis. Abnormally delayed resolution will be mentioned below.

#### SPECIAL PECULIARITIES AND ANOMALIES IN THE COURSE OF PNEUMONIA.

1. *Pneumonia in Children*.—Beside the common lobular pneumonia there is also a pure, lobar, croupous pneumonia in children, which is by no means so rare as some authors formerly supposed. An initial chill is seen only\* in older children; initial vomiting, however, is very common in children. In many cases severe cerebral symptoms, like delirium, drowsiness, or convulsions, obscure the pulmonary symptoms at first. The further course, the development of physical signs, the fever, and the complications, are quite analogous to the appearances in adults. The pneumonic sputum is only exceptionally to be observed in children under eight years of age.

2. *Pneumonia in old people* is always dangerous. It may begin suddenly, as in people of middle age, but often it begins more slowly and insidiously. Its course is marked by the speedy onset of great weakness and debility. Nervous symptoms, like delirium, are not infrequent.

3. *Drunkard's Pneumonia*.—We see croupous pneumonia in drunkards with remarkable frequency. The clinical course is characterized by the develop-

ment of delirium tremens, usually in the first days of the disease. The patient's mind is disturbed, he is very restless, constantly tries to get out of bed, and he fumbles night and day with his bed-clothes or articles of clothing. The alcoholic character of the delirium is shown by the patient's whole manner, the tremor of the hands and tongue, and the usually happy character of the delirium. The delirium refers to his favorite beverages, his previous boon companions, etc. He becomes tearful or raving only when forcibly restrained. He may think himself involved in the tavern brawls. The alcoholic delirium is almost always associated with hallucinations. The hallucinations of little moving black figures are especially characteristic. They are either animals, rats or beetles, or little black men, and they give him much trouble. The subjective symptoms of pneumonia are wholly in the background. No delirious patient with pneumonia complains of cough, pain in the chest, or dyspnoea. Careful objective examination is the only thing that confirms the diagnosis. Very often patients with a happy delirium serve to entertain those about them, until suddenly very severe symptoms arise, and they become somnolent and succumb, with the symptoms of pulmonary oedema. The prognosis of every case of drunkard's pneumonia, therefore, is to be regarded as very unfavorable.

4. *Pneumonia in Pre-existing Chronic Diseases.*—Croupous pneumonia is occasionally seen in all forms of chronic disease. It is especially dangerous in persons who are already enfeebled, or afflicted with chronic cardiac or pulmonary disease, like phthisis or emphysema. The pneumonia which often attacks patients with emphysema is clinically important, since emphysema may render the objective evidence of pneumonia very difficult. The croupous exudation does not completely fill the dilated alveoli; hence decided dullness and bronchial breathing are absent.

5. *Pneumonia with Late or Slight Localization—Central Pneumonia.*—Cases are quite often seen whose beginning, course, and subjective symptoms correspond throughout to a croupous pneumonia, but in which the objective evidence of pneumonic infiltration evades the most careful examination. The disease begins with a chill, the fever is high, the patient complains of pain in the chest, which is usually slight, there is perhaps herpes, but only on the fourth, fifth, or sixth days can we make out anywhere any bronchial breathing or crepitant râles. In other cases even the crisis may set in before we are able to localize the pneumonia with certainty. In most of these cases we probably have to do less with an actual late localization than with a central infiltration which nowhere approaches the periphery, and hence is made out objectively only late or not at all. A careful examination of the sputum is of the greatest diagnostic importance, since it sometimes has a perfectly characteristic appearance in spite of the absence or the indefinite character of the physical signs. If there is no sputum, the diagnosis must of course remain very uncertain. In such a case under our own observation a slight pleuritic friction-sound was the only thing heard and that not until the day after the crisis, but this, added to the rational signs, made the diagnosis of pneumonia certain.

6. *Typhoid Pneumonia—Asthenic Pneumonia.*—By typhoid pneumonia we mean those cases in which, beside the local pulmonary symptoms, which may be either slight or well marked, there are remarkably severe general symptoms. The cases do not often begin as suddenly as ordinary pneumonia, but more gradually, like typhoid. Even at first the general symptoms, such as great dullness, loss of appetite, or headache, predominate over the thoracic symptoms. At the height of the disease there is a decided typhoidal state, stupor, delirium, a very dry tongue, great general weakness, and also enlargement of the spleen, and fre-

quently mild jaundice, albuminuria, etc. Such cases are to be regarded as pneumonia with an unusually severe general infection. They sometimes occur in epidemics. It is said that pneumonia of the upper lobes shows a somewhat more frequent tendency to severe nervous symptoms than pneumonia of the lower lobes. Recovery from this typhoid or asthenic pneumonia, which may last two weeks or more, often follows by lysis. Typhoid pneumonia is by no means a sharply defined disease. The term serves merely as a short name for the grave constitutional disturbance. Clinically it is impossible to distinguish it sharply from pneumonia migrans, bilious pneumonia, and other forms.

The croupous pneumonia which comes on in the course of genuine typhoid is aetiologically quite different, but in diagnosis it is often very hard to distinguish it. Here we have typhoid with a secondary localization in the lungs—"pneumotyphoid" (see page 13)—which is rare. In the cases first described, however, we had a pneumonia with very marked general infection—"typhoid" symptoms. The only things which render an accurate differentiation of the two diseases possible in such cases are observation of the whole course of the disease, attention to all the single symptoms, such as the intestinal symptoms, and roseola, and the aetiological relations, so far as we can learn them.

7. *Pneumonia with Delayed Resolution.*—While the resolution of pneumonia is complete, as a rule, in three days to a week after the occurrence of the crisis, there are cases in which this process demands a much longer time. Not infrequently, and particularly in severe cases of pneumonia, one sees after the crisis a surprisingly rapid disappearance of all the physical signs, while, on the other hand, recovery is sometimes remarkably slow in apparently mild cases; but this rule is of course not universal, and not without exceptions. The course of the disease is often enough precisely the opposite. Just what are the conditions upon which the rapidity or the slowness of resolution depends we do not know. Sometimes unfavorable constitutional conditions, such as anæmia, debility, phthisical tendencies, and kyphoscoliosis appear to delay resolution. Sometimes, on the other hand, no such explanation can be found. It seems to us that at certain times all the cases of pneumonia exhibit more of a tendency to delayed resolution than at others, so that it is not impossible that there are variations in the pathological process itself. Perhaps, however, secondary pulmonary diseases play a part in the phenomenon.

With regard to the symptoms of delayed resolution, there are various forms. In the first place, we see cases where the crisis takes place in the usual way, and the temperature thereafter remains permanently normal. The patients perhaps feel quite well, and are troubled little by thoracic symptoms; nevertheless, the dullness upon percussion remains unchanged, or diminishes at best very gradually, and the bronchial breathing or subcrepitant râles can still be heard. All the signs diminish very slowly, sometimes occupying several weeks in their disappearance, and then complete recovery ensues. In other cases there is no distinct crisis, but the fever continues, although lower than at first, and the physical signs remain to a greater or less extent. At the end of two or three weeks, or even still later, the fever slowly ceases, and thereupon normal resonance and vesicular breathing gradually return. Still another course, which differs somewhat from those already described, and of which we have repeatedly observed typical instances, is the following: The patients remain free from fever for about a week after the crisis appears. During this time the dullness remains, and the bronchial breathing, although not very loud, is constant. Then a moderately intermitting fever comes on again, with an increase of temperature to about  $102^{\circ}$  or  $103^{\circ}$  ( $39^{\circ}$ – $39.5^{\circ}$  C.). This fever may last from two to four weeks, or even longer. Only occasionally, if ever, do we hear a râle over the affected portion of the lung. A

moderate contraction of the affected side gradually appears. Then the resonance slowly becomes clearer, and the respiration becomes louder and vesicular again. The fever disappears, and complete recovery finally takes place. In many other cases of delayed resolution there is also a marked absence of râles and a mild degree of contraction. The differentiation from secondary pleurisy is here often very difficult, except by tapping the chest. Again, it is not very exceptional to observe delayed resolution and secondary pleurisy simultaneously in the same patient.

If there is really merely delay in the resolution and no distinct secondary disease (see below), complete recovery will almost always come at last.

8. *Termination of Pneumonia in Phthisis, Contraction of the Lungs, Pulmonary Gangrene, or Pulmonary Abscess.*—Three terminations of pneumonia are ordinarily mentioned as unusual and anomalous—the termination in "chronic pneumonia," in gangrene, and in abscess.

Concerning the termination in chronic pneumonia, we have already mentioned a process belonging here, the termination in contraction with ultimate recovery; but in rare cases the contraction is persistent. From the complete lack as yet of careful post-mortem examinations, we can not give fuller details as to the anatomical process in these cases (hyperplasia and retraction of the inter-alveolar connective tissue?).

By the "termination in chronic pneumonia" we usually mean a termination in phthisis—that is, tuberculosis. With our present conception of the two diseases there can, of course, be no question of an actual transition from one to the other. Accordingly, where a clear case of phthisis develops as a sequel to genuine croupous pneumonia—which, however, is quite rare—either the pneumonia develops upon a pre-existing tuberculosis, or tuberculosis develops after the pneumonia in a person predisposed to tubercle.

The transition from pneumonia to pulmonary gangrene is sometimes seen, especially in old and weak individuals. Here, too, in our opinion, a new infection, with a foul and putrid substance, must always take place, and this excites the gangrene. The previous pneumonia furnishes only the occasion for the development of gangrene, and perhaps prepares the soil for the agents of decomposition. The development of gangrene is appreciated clinically from the change in the sputum.

The transition from pneumonia to pulmonary abscess is very rare. We can not decide whether a specific further cause is also needed for this, or whether the pneumonic process may exceptionally go on into the formation of abscess. The transition to an abscess may be recognized by the character of the sputum, which contains fragments of pulmonary tissue, such as elastic fibers, beside abundant pus. Besides that, we find, on microscopic examination of the sputum in abscess, sometimes scales of cholesterine (Fig. 25) and hæmatoidine crystals; the latter may be so abundant as to give the expectoration a brownish color. Sometimes we have seen a peculiar greenish color of the sputum. The signs of a pulmonary cavity are found if the abscess bursts.

**Diagnosis.**—No special remarks on diagnosis need to be added to the description we have given of all the important symptoms which may occur in croupous pneumonia. We should pay particular attention to the sudden onset, the characteristic spu-

FIG. 25.—Cholesterine crystals.

tum, the physical signs, the frequent occurrence of herpes on the face, and finally to the whole course of the disease, especially to the temperature curve. We will discuss the differential diagnosis between pneumonia and pleurisy with effusion more fully in the description of the latter affection.

**Prognosis.**—Croupous pneumonia belongs in general to the benignant infectious diseases. The great majority of cases, in previously strong and healthy individuals, run a favorable course, and end in complete recovery. On the other hand, pneumonia brings a number of perils with it, the knowledge of which should always make us cautious in giving a prognosis.

A grave danger lies in the extension of the process. If the advance of the pneumonia can not be stopped, if the whole of one lung is involved, and, besides that, a great portion of the other lung, the diminution of the respiratory surfaces forms a factor which may give rise to a fatal termination.

A further danger lies in the onset of certain complications. An intense pleurisy, with effusion, especially if purulent, causes greater difficulty in respiration, and thus increases the danger. Still worse is a sero-fibrinous or purulent pericarditis, which, in not very rare cases, is revealed at the autopsy as the special cause of death. We must note, however, that recovery sometimes finally takes place in spite of an empyema or of a purulent pericarditis. The complication with a purulent meningitis, which is fortunately very rare, is probably invariably fatal.

The dangers of general infection (or perhaps a more correct expression would be general intoxication) occupy a subordinate place in pneumonia, on the whole, in comparison with other infectious diseases, like typhoid, but the constitutional state is important in the so-called typhoid, asthenic pneumonia. Sometimes unusually severe and malignant forms of pneumonia, with a high mortality, occur in epidemics and endemics, but these cases are often characterized by the extent of the local process, or by the development of the dangerous complications mentioned above.

The individual circumstances of the patient play the most important part in the prognosis of pneumonia. While a constitution that was previously healthy and uninjured usually survives the disease, one that was previously weak and diseased readily succumbs. In this fact lies the danger of pneumonia in old, weak, badly nourished persons, and in persons with a pre-existing emphysema, kyphoscoliosis, heart disease, etc. In this, too, lies the great danger of every pneumonia in drunkards. Since the nervous system is much affected by chronic alcoholism, we very often see outbreaks of delirium tremens in pneumonia, which come on very readily. In like manner the other nerve-centers are weakened and incapable of resistance, especially the regulatory centers for the heart and respiration. Hence we can understand why even moderate drinkers, though previously strong and well to all appearance, succumb to pneumonia from insufficiency of the heart and lungs.

If we ask upon what symptoms our prognosis in any given case should depend, we must reply that no single factor can be given especial prominence. Chief stress must always be laid upon the state of the lungs and the respiration, but attention must also be given to the general condition, the heart's action, the height of the fever, etc. The worst dangers of pneumonia have just been mentioned.

Of the abnormal terminations of pneumonia, contraction gives the best prognosis, but recovery, or at least a marked subsidence of all the symptoms, may sometimes take place after gangrene and abscess.

**Treatment.**—Many of the milder cases of typical pneumonia need no special active treatment when the disease on the whole takes a favorable course. Most cases get well under, or, we can almost say, in spite of any treatment. From the

method of treatment by large bleedings, which was formerly customary, and also by certain drugs which are even now occasionally used—we refer especially to *veratrine*—we should expect an injurious effect, and not a favorable one; and yet even with such treatment many cases of pneumonia recover.

[In robust individuals, with a full, hard pulse and great oppression of breathing, venesection affords a prompt relief to be obtained in no other way.

In general, the main indications for treatment are, as in other acute self-limited diseases, to support life until the disease has run its course.]

We do not know a remedy which can in any way exert a favorable influence upon the pneumonic process itself. The treatment of pneumonia must therefore be purely hygienic and symptomatic, but in this respect it can accomplish very much.

The symptoms which are usually prominent in every pneumonia, even in the milder cases, and of which the patient is especially desirous to be relieved, are the pain in the side, the troublesome cough, and the difficulty and distress in breathing. Since the respiratory symptoms, as we have seen, are partly due to the pain, as this improves the patient's breathing often undergoes a decided improvement. For the pain, we may first mention a number of external applications to the skin on the affected side. An ice-bag sometimes gives marked relief. Many patients can not bear this, but prefer warm poultices or cold wet compresses. The application of mustard plasters or dry cups to the skin may be of advantage. Subcutaneous injections of morphine, however, are the most effective remedy, and are often indispensable. There is no reason why we should not use this remedy, with care and in moderate doses, for the relief of pain; and, as the disease is of short duration, we need not particularly fear the morphine habit. Small doses of morphine, subcutaneously or by the mouth, may also be required to alleviate the cough.

Local blood-letting is a remedy the action of which can not be explained physiologically, and yet experience has shown that it is of undoubted advantage. The relief which many patients feel after the application of ten or twelve leeches to the affected side is very striking; but we should prescribe them only when there are severe symptoms at the beginning of the disease, and in persons who were strong and healthy before the attack. Wet cups accomplish the same thing, but the effect is somewhat more powerful, and hence they should be reserved for strong and robust persons, such as laborers.

The tepid bath serves as the most effective means of improving the respiration, of aiding expectoration, and of stimulating and refreshing the whole system. We hold it useless, if not injurious, to give a patient baths if the disease is progressing favorably, for almost every bath has some disagreeable feature. These disadvantages, however, are always less, in severe cases, than the benefit and improvement which baths give the patient, and which most patients recognize with gratitude. The main point is that the patient should make no physical exertion while in the bath, that he should be lifted into it, held and supported while in it, and lifted into bed again after it. Since the baths are given primarily not on account of the fever, but to improve the respiration, and because of their favorable influence on the nervous system, their temperature need not be especially low. We give them from 85° to 90° (24°-26° R.); somewhat warmer with sensitive and weak people, and cooler, down to 77° or even 72.5° (20°-18° R.), with strong people, or with very high fever or severe nervous symptoms. We need not employ more than two or three baths a day, and at night we employ them only when there are threatening symptoms. The favorable action of the baths is especially seen in the great relief and refreshment that the patient feels. The respiration is quieter and slower, but deeper. The patient often falls into a quiet sleep after the bath.

Antipyretics are seldom useful in pneumonia. Even if the temperature rises very high, up to 106° (41° C.), cool baths are sufficient to avert the dangers of an increase of bodily heat. If any antipyretic must be used, antipyrine is to be preferred.

Expectorants are much used, especially since in practice we seldom can avoid giving some internal remedy. Among the most useful are infusion of ipecacuanha, benzoin, liquor ammonii anisatus, and tartar emetic, once held to be a necessary specific against pneumonia (!). Finally, digitalis may be indicated under some circumstances with a weak and frequent pulse, either in powder or in an infusion of about 1 to 100.

We must give the greatest attention in all severe cases to keeping up the patient's strength. We must therefore take care to furnish an easily digestible but nutritious diet. Meat in small pieces, cut up fine or scraped, may be freely allowed if the patient has an appetite for it, but during the first days of the disease we are usually confined to giving soups, milk, and eggs. As soon as the signs of more marked general weakness appear, and the pulse becomes smaller, we must order stimulants, wine, strong *café noir*, or, still better, ether or camphor. The latter is best given subcutaneously in severe cases, dissolved in olive-oil, in a ratio of one to four. If the patient swallows well, we may give it in wine, two grains (grm. 0.1) every one or two hours.

We have yet to make some remarks upon the very extensive use of large amounts of alcohol in pneumonia. Without doubt a free use of alcohol is necessary in drunkards, especially when delirium tremens is beginning or is already pronounced. Since the withdrawal of any poison that is taken habitually, like nicotine or morphine, may excite the severest symptoms, the sudden withdrawal of alcohol from drunkards may have the worst results, while, if we give an abundant supply of the stimulant to which the nervous system is accustomed, we sometimes succeed in avoiding the onset of severe nervous symptoms, like collapse and failure of the heart and respiration. It is quite a different matter with patients who before their illness have not been accustomed to take alcohol at all, or who took it only in small amounts. It may be true that in these cases small amounts of wine may have a stimulating and exciting action, although we never could satisfy ourselves of the often praised influence of alcohol upon the action of the heart. We hold it, however, unjustifiable to force large amounts of alcohol indiscriminately upon every patient with pneumonia, perhaps in spite of great resistance on his part. Why should we expect sick persons to bear doses of alcohol which have only bad results on healthy men unaccustomed to them?

[Few American physicians of any experience will accept the reasoning of the author on the employment of alcoholic stimulants in those not accustomed to their use.

The toxic effects of alcohol are as undesirable in pneumonia as in any other disease, but there are few affections in which so great tolerance is shown for this agent. The chief indications for its exhibition are derived from the pulse and the first cardiac sound at the apex. A flagging heart calls for alcohol, the effect of which on the symptoms and on the circulation is to be carefully watched; the quantity is to be diminished, increased, maintained, or the agent is to be omitted entirely, according to the conditions present in the individual case. I am no advocate of indiscriminate alcoholic stimulation; but I believe that lives have been frequently saved in the past, and will be saved in the future, by the judicious and sometimes extremely free use of this class of remedies in acute pneumonia. Inhalation of oxygen has won a prominent place in the treatment of severe pneumonia of late years, and cases are reported in which life seems unquestionably to have been saved by it. In a considerable number of cases the editor has seen only

one which could come under this class. He has seen, however, marked temporary improvement in pulse and respiration, with diminution of cyanosis and induction of relatively quiet sleep. But the oxygen must be given in large quantities, sometimes continuously. If its inhalation fatigues the patient, the gas may be allowed to escape before the mouth or under the nose of the patient. The objection to the efficient use of oxygen in some cases is the expense of perhaps some hundreds of gallons a day at five cents a gallon.]

The treatment of complications follows the ordinary rules which have been given under the individual affections. We must also mention that, in delirium tremens, tepid baths with cold douches sometimes have a very good effect. Besides this, we may try subcutaneous injections of strychnine, seven to fifteen minims of a one-per-cent. solution, once or twice a day. We can not wholly dispense with narcotics, such as morphine and chloral, but we must warn against the imprudent use of large doses of chloral, above thirty-five grains (grm. 2.5).

## CHAPTER VI.

### TUBERCULOSIS OF THE LUNGS.

(*Pulmonary Phthisis. Pulmonary Consumption.*)

#### GENERAL PATHOLOGY AND ÆTIOLOGY OF TUBERCULOSIS.

EVER since Bayle, in 1810, demonstrated the extensive distribution of peculiar nodules in the various organs, and their relation to pulmonary consumption, few questions have so taxed clinical observers and pathologists as those relating to the cause and nature of tuberculosis. Harmony could not be reached, however, so long as the criterion for the decision of the questions was sought in the presence of definite anatomical changes, which were regarded as specific of tuberculosis. Laennec considered the peculiar change in the tubercular products, which later was named caseation by Virchow, to be characteristic, and called everything tubercular where it was found. He distinguished the isolated tubercle from diffuse, tubercular, cheesy infiltration. Thus Laennec recognized that many processes were allied whose affinity was often disputed afterward, and has only recently been established, such as the affinity between "scrofulous" enlargement of the glands and tuberculosis. Another opinion became quite prevalent, after Virchow discovered that precisely the same anatomical process as tubercular caseation was also found in inflammatory products, which were certainly not tubercular, and in cancerous ulcerations. Hence Virchow made a sharp distinction between tubercle and those new growths and inflammatory processes which had become cheesy. The anatomical criterion of tuberculosis was, in his view, the presence of the miliary tubercle, a gray nodule, the size of a millet-seed at the largest, made up of cells like lymph-corpuscles. The study of the finer structure of the miliary tubercle was now pushed most eagerly by Wagner, Schüppel, Langhans, and others, but they were unable to reach perfect harmony regarding its origin and significance.

As long ago as 1865, however, a discovery was made which pointed unequivocally to the only way which could lead to a correct knowledge of tuberculosis. It was the fact, discovered by Villemin, that tuberculosis can be produced artificially by inoculating healthy animals with small amounts of tubercular and cheesy substances. Although doubted and misinterpreted at first in various quarters, the fact that tuberculosis can be transmitted, and consequently the fact of its infectious

character, must now be regarded as proved beyond a doubt. In the general change which our opinions upon the nature of infectious diseases have undergone, especially in the last few years, the existence of a specific, organized cause of tuberculosis, too, had to be assumed. Klebs, and later Cohnheim, had already without reserve defined tuberculosis as a specific, infectious disease and, sooner than we dared to hope, R. Koch discovered the special carriers of the disease in the shape of the tubercle bacilli, in the year 1881. The definition of tuberculosis no longer rests upon any external anatomical character. Every disease is tubercular which is excited by the pathogenic action of a specific kind of bacteria, the tubercle bacilli discovered by Koch.

The pathogenic bacteria of tuberculosis belong to the group of bacilli. The tubercle bacilli are rod-like, of small diameter, slightly rounded at their extremities, and either straight or somewhat bent. Their length is perhaps a fourth or a half that of the diameter of a red blood-corpuscle. In the interior of these rods it is not seldom possible to distinguish very minute colorless spots which are probably to be regarded as endogenous spores. The tubercle bacilli have no independent motion whatever. Their reaction to certain coloring matters is very characteristic, and of the highest importance with regard to their recognition (see below). We know with absolute certainty that the tubercle bacilli are always present in all the different forms of pulmonary tuberculosis, both in the lung itself and in the expectoration (*vide infra*), and also in tubercular diseases of other organs, like the brain, the intestines, the spleen, the liver, and the kidneys, and also in "scrofulous lymph-glands," in "fungous" diseases of the bones and joints, and in the so-called lupus, which is nothing but a local tuberculosis of the skin. Precisely the same bacilli are also found in the "spontaneous" tuberculosis of animals, such as monkeys, puppies, and guinea-pigs, and in every tuberculosis that is artificially produced in animals by inoculation. Finally, by the discovery of tubercle bacilli in the "pearly distemper" of cattle, the identity of this disease with tuberculosis—an identity which had already been established by experiments in inoculation—was confirmed anew.

Koch, by his successful "pure cultures" and inoculations with the cultivated bacilli, has established the fact that these bodies, known as tubercle bacilli, are to be regarded as organized, and as the special cause of tuberculosis. Bacilli coming from any fresh product of tubercular disease may be cultivated at a constant temperature of 98° to 100° (37°-38° C.) upon blood-serum which has been stiffened by heating, and upon several other artificially prepared soils. In this cultivation they show certain characteristic properties in their growth, which can not be fully described here, and they multiply to an unlimited extent. In this way we can keep up perfectly "pure cultures" of tubercle bacilli. Inoculation experiments tried with them on all sorts of creatures always give a positive result. The animals fall ill, lose flesh, and finally die, and at the autopsy we find undoubted tubercular disease of the internal organs, which may be more or less extensive. The most instructive inoculations are those into the anterior chamber of the eye in puppies or guinea-pigs, which were first tried by Cohnheim and Salomonsen. After an incubation of two or three weeks we see here very plainly an eruption of the first nodules of tubercle in the iris, and the tuberculosis spreads to the other organs of the body later.

#### ÆTIOLOGY OF TUBERCULOSIS IN MAN.

The distribution of tubercle bacilli must be remarkably extensive, for tubercular diseases occur in almost every country on earth. The predisposition of mankind to the disease is also very great, and thus we understand the frightful

fact, which statistics show, that nearly one seventh of all deaths are from tuberculosis! It has neither been proved, nor is it probable, that tubercle bacilli multiply outside of the human body, like the bacilli of splenic fever, since they can develop only in a constant and uniformly warm temperature between 85° and 104° (30°-40° C.). We must therefore regard them as true parasites, which can live—that is, which can propagate and multiply—only in the bodies of animals, but they seem to preserve their virulence and their ability to multiply outside of the body for a long time. Phthisical sputum may be used for inoculation with success, even if it has been dried for several weeks. The tubercle bacilli also resist most chemical reagents, like nitric acid, very decidedly.

If the body becomes infected, then, with tubercle bacilli, it is always probable that they have come from some other individual—man or beast—with tubercular disease. We need not mention how numerous the opportunities for infection may be, considering the present general distribution of tuberculosis. The chief stress in this respect is to be laid upon the expectoration of phthisical patients, which contains the bacilli. This dries on the floor, on the linen, and on other objects, and then the small particles which contain the germs of infection are carried off by the air. The view most generally held is that the material which contains the bacilli or spores is taken into the body, in the majority of cases, along with the inspired air. This is probable, because, in most cases, tuberculosis has its starting-point in the air-passages, the lungs, or larynx. Inoculation experiments show that the first extension of the process depends upon the point of inoculation. If it be in the anterior chamber of the eye, the first nodules appear in the iris, as we have said; if it be in the abdominal cavity, we have first a tuberculosis of the peritonæum; if the infectious matter be inhaled, we have first a tuberculosis of the lungs. For several years Tappeiner and others have experimented with inhalations of powdered tuberculous sputa at the Munich Pathological Institute. Pulmonary tuberculosis could always be produced by these inhalations in the animals experimented upon. Hence it seems very probable that, in tuberculosis in man, the infectious matter is taken directly into the air-passages by the breath. In this way it sometimes, though rarely, attacks the upper air-passages, as in primary tuberculosis of the nose, the pharynx, and the larynx, but more frequently it affects the deeper portions of the respiratory apparatus, as in primary tuberculosis of the lungs and bronchi.

We must also consider other methods of infection, first among which is the possibility of infection of the intestinal canal, from swallowing the infectious material. The transmission of tuberculosis from domestic animals to man plays a part in this connection which perhaps is not unimportant. Since the pearly distemper in cattle is identical with tuberculosis in man, the use of the flesh of such animals as food furnishes a possible means of infection. It is a still more important circumstance, however, that, when pearly nodules are present on the udder, the milk of the diseased animal may be polluted by tubercle bacilli, and that the use of such milk as food, when it is uncooked, certainly involves the danger of the transmission of tuberculosis. Primary tuberculosis of the intestines, however, does not seem to be very frequent, probably because the tubercle bacilli which have been swallowed are usually destroyed in the stomach.

In some cases the tubercular infection may probably arise from little fissures and excoriations of the skin. In this way we get either a local tuberculosis of the skin, like lupus, or the bacilli are carried by the lymphatics to the neighboring glands of the neck or axilla, establish themselves there, and set up a tubercular disease in them. In conclusion, we have still to mention that the apparently primary appearance of tuberculosis in the genito-urinary apparatus leads us to think of the possibility of an infection of the genital or urinary organs.

Considering the wide distribution of the tubercle bacilli, and the many chances for infection, it seems wonderful that in spite of it so many men escape the disease. One factor, which has been already mentioned by Koch, must be borne in mind, however, and that is the extremely slow growth of the tubercle bacilli. This is the reason why the bacilli do not always remain in the body, but in many cases are eliminated again before they have gained a definite foothold.

Individual predisposition, however, is another factor which perhaps is still more important—a factor which we can not well explain, but which we can not get on without, at the present time, in the pathology of many infectious diseases. In our conception of most of the other infectious diseases, as well as of tuberculosis, we must assume provisionally an unequal predisposition to disease in different individuals. Only a part fall ill of all who are exposed to the action of the poison. These are persons in whom it is particularly easy for the poison to establish and propagate itself.

We have long considered people with a generally feeble physical constitution as especially liable to tubercular disease. We speak of a "tubercular habit" (*vide infra*). In this connection we must, of course, remember that much that we once regarded as merely the signs of a special predisposition to disease is really the expression of a disease that already exists. If, for example, we once affirmed that "scrofulous" children had a special predisposition to tuberculosis, we know now that the so-called scrofulous diseases of the mucous membranes, the lymph-glands, and the bones, are the results of an existing tuberculosis; or, at least, that this is so in a large number of cases.

We now believe that many evil influences which were once thought to be causes of tuberculosis act only in increasing the predisposition to the disease. Insufficient food, bad air, severe illness, childbirth, want, and care—these alone, of course, can never produce tuberculosis; but we can easily imagine that the body which has become weakened affords less resistance to the injurious influence of the tubercular poison than does the strong and healthy body. Thus it seems to us, from our own observations, to be in the highest degree probable that chronic alcoholism increases the liability of the individual to tuberculosis.

People used often to speak of the transition of other affections of the lungs into pulmonary consumption—that is, into tuberculosis. It was imagined that an old bronchial catarrh, croupous inflammation of the lungs, or catarrhal pneumonia in measles, or whooping-cough, could readily become "tubercular." It goes without saying that such an idea is no longer tenable, after the demonstration of the specific, infectious nature of tuberculosis. If we see a pulmonary tuberculosis develop as a sequel of any other affection of the lungs, we can express the relation between the two diseases only in this way, that the first disease furnished a favorable soil for infection with tubercular virus, and that, consequently, the tubercle bacilli could more easily take root upon a previously diseased mucous membrane than under normal conditions; moreover, there is no doubt that many of the affections, whose "transition into tuberculosis" we once assumed, are themselves tubercular. This is the case, as we shall see, in many cases of pleurisy. No one will now admit the truth of the theory, which Niemeyer once vigorously defended, that a primary pulmonary hæmorrhage could cause the development of pulmonary phthisis. Certainly, in the cases which apparently support such an opinion, the pulmonary hæmorrhage is not the cause, but a symptom, of pulmonary tuberculosis.

No single factor, however, of those which favor the predisposition to tuberculosis, plays so manifest and so visible a part as does heredity. The fact of the heredity of phthisis meets us with such uncommon frequency that it must have forced itself upon the notice of the older physicians. In the great majority

of all cases of phthisis we can make out, by close questioning, that in the family, either among the older members or among the brothers and sisters, one or more cases of tubercular disease have already occurred. The closer we investigate, and the more we search for some one of the different forms in which tuberculosis can show itself, like pleurisy, or affections of the bones and joints, the more frequently we can make out this hereditary predisposition.

While there can be no doubt of the facts themselves, their explanation is by no means a simple one. At all events, the question of the heredity of tuberculosis now needs to be studied with renewed care. The hereditary character of tuberculosis may very well harmonize with its infectious character.\* We might assume in this case a perfect analogy with syphilis—namely, a transition of the infectious material from the parent to the child before birth. There is only one striking difference between syphilis and tuberculosis—that the children of syphilitic parents very often come into the world with definite signs of infection, while congenital tuberculosis in this sense is an extremely rare occurrence. We must accordingly compare tuberculosis to that form of hereditary syphilis (*lues hereditaria tarda*) in which the first symptoms of the affection come on at a late period.

Since certain considerations, however, constantly oppose such a theory, we are of late disposed to assume that, as a rule, tuberculosis in itself is not inherited, but only the predisposition to tubercular disease. This opinion agrees with the facts that members of a family in which tuberculosis prevails very often show the so-called tubercular habit even without any real tubercular disease; and that they often have "weak lungs"—that is, that they easily get out of breath, and manifest a distinct tendency to catarrh of the respiratory organs. Another fact, which to a certain extent may be regarded as an argument against the assumption of a direct hereditary transmission of the disease, is that, in cases of apparently hereditary tuberculosis, as a rule those organs first show evidences of disease which are most exposed to an infection from the outer world—namely, the lungs and larynx.

Meanwhile there is a third possibility to be considered with regard to the "inheritance of tuberculosis." Many cases of apparently inherited tuberculosis are, in all probability, to be explained by the fact that children or relatives who are constantly in the company of a patient with phthisis are decidedly more exposed to the danger of infection than other persons. This is also the reason why tuberculosis is very often conveyed from husband to wife, or *vice versa*, of which we might furnish a series of examples from our own experience.

The age of the patient has an important influence upon the predisposition to tubercular disease. Pulmonary tuberculosis occurs with special frequency in youth, between fifteen and thirty. It is not rare in children. After forty it is much rarer in its pronounced forms, but it is seen even in the most advanced age. Slight tuberculous changes are very frequently found at autopsy in the lungs of old persons. These changes have, as a rule, no clinical significance.

It has not yet been shown that sex has a special influence upon the predisposition to the disease.

---

\* Jani has made the very interesting observation, that a few tubercle bacilli may be found in phthisis in the vas deferens and the prostate, or in the folds of the lining membrane of the tubes, without apparent disease of these parts. Whether this, however, explains the hereditary transmission of tuberculosis, is as yet doubtful.

## PATHOLOGICAL ANATOMY OF TUBERCULOSIS, ESPECIALLY OF PULMONARY TUBERCULOSIS.

If now we inquire wherein consists the injury which the tubercle bacilli inflict upon the body, the first point to emphasize is that the action of the tubercle bacilli is at first invariably purely local. Tuberculosis does not belong to the "general infectious diseases," in which the infection of the whole organism, the "general infection" of the body, predominates over the local disturbances. The essence of tuberculosis, at least in the great majority of cases, is the local disease. The tubercle bacilli give rise to definite anatomical changes in the organs where they settle, and the consequent disturbance of function in the organ has an effect on the rest of the body. In many cases the whole body may be so little affected that we may be justified in saying that there is a purely "local tuberculosis."

The danger of tubercular diseases, however, consists in the fact that the local affection often attacks the most important organs, as the lungs and the brain, and sets up such extensive anatomical changes in them that because of these changes alone it becomes impossible for life to continue longer. Besides this, the infection in many cases does not always confine itself to one organ, but the infectious material extends over the body by ways and means which we shall learn in part later on, and attacks one organ after another, or even many at once. Finally, it is to be said that the peculiar character of the changes caused by tuberculosis explains why these are often the cause of manifold secondary processes, such as toxic effects and secondary infections. Thus arise fever and other important symptoms, which will be minutely considered later.

The entire local action of the tubercle bacilli—that is, the pathological anatomy of tuberculosis—is almost wholly independent of the organ attacked. Tuberculosis belongs to the group of so-called "infectious tumors"—that is, the local action of the tubercle bacilli consists chiefly in the production of a proliferation and accumulation of cells at their place of settlement, which is termed a tubercular new growth.

According to the later investigations of Arnold, Baumgarten, and others, the process begins with hyperplasia of the normal tissue, both of the interstitial and of the epithelial cells. In this way are developed the so-called epithelioid cells and the giant cells. The next step in the process is the migration of numerous leucocytes from the surrounding blood-vessels. The leucocytes, or round cells, collect about the above-mentioned new-formed cells, and may finally completely cover them. A network, or reticulum, is found between the individual new-formed cells and the wandering cells. This probably represents the remains of the original interstitial tissue, crowded apart by the increased number of cells. There is no new formation of vessels. The tubercle contains no blood-vessels. The tubercle bacilli lie especially inside the giant cells, but also in their vicinity.

If these changes have progressed far enough, they become visible to the naked eye as a small, circumscribed grayish point, which is called a miliary tubercle. From these minute nodules the disease itself obtained its name of tuberculosis. By approximation and coalescence of neighboring tubercles—for these keep developing because of the spread of the local infection—the tuberculous formation continually extends itself, and thus are gradually formed the large tubercular nodules, and finally the diffuse tuberculous new growth or the diffuse tuberculous infiltration.

The tuberculous new growth, as such, can scarcely ever be distinguished histologically from other infectious tumors, such as those seen in syphilis and leprosy. Tuberculosis, however, has a characteristic difference in its final stages of cheesy degeneration and eventual disintegration of the new-formed tissue, processes

which are apparently connected with the absence of blood-vessels and the consequent deficiency of nutrition of the new formation. Both the tuberculous infiltration and also the portions of the original tissues inclosed by it perish, lose their nuclei, and finally become disintegrated. The manner in which they are destroyed—namely, "fatty degeneration"—belongs in the group of the so-called coagulation necroses. This process is recognizable to the naked eye, because the tuberculous infiltration when it becomes thus degenerated takes on a pronounced yellowish color. Wherever the necrotic portions of tissue are superficially situated they are cast off, giving rise to tuberculous ulcers.

Alongside the tuberculous new formation there are found in the organs affected with tuberculosis various inflammatory processes, either simple or suppurative or hemorrhagic. We may therefore surmise that the tubercle bacilli, besides their characteristic effects, act simultaneously in another rôle as excitants of inflammation; but it is very probable, and especially so in pulmonary tuberculosis, that many of the inflammatory changes which arise are not peculiar to the tuberculosis as such, but are to be regarded as secondary processes (*vide infra*).

As regards the special anatomical processes and appearances in pulmonary tuberculosis, the tubercular change usually begins in the walls of the smallest bronchi, or not rarely in the alveoli themselves. The disease does not begin, however, in many different parts of the lung at once, but probably in one or two circumscribed spots only, and in a great majority of cases in one apex. We do not know why the apices are so often the starting-point of phthisis, but perhaps it is because of their relatively slighter expiratory power, which renders them a favorable lodging-place for the tubercle bacilli.

The tubercular infiltration begins in the bronchial wall and extends gradually to the periphery. A tubercular peribronchitis arises as a result of the original tubercular bronchitis. The infectious material, as soon as there is any superficial ulceration, is readily carried from the original focus of the disease to other bronchi, by means of the current of air, and thus the disease gradually extends. Tubercular peribronchitis is usually easily recognized with the naked eye. We notice the little lumen of the bronchus in the middle of the "cheesy" nodule, which at first is gray and later yellowish. Many of the adjacent nodules run together in part, and even entirely. The lumen of the bronchus is either wholly plugged by the infiltration, or the destruction of the necrotic cells begins in the midst of the peribronchitis. In the latter case the lumen is enlarged to a little irregular hole—the first beginning of the formation of a cavity.

The alveolar tissue of the lung can not long remain unaffected, with such a disease of the smaller bronchi. Lobular atelectasis, the necessary result of every permanent bronchial obstruction, must arise, but this soon passes into a lobular pneumonia, which from its specific nature later becomes caseous. We can not go into the histological details here. The alveoli are filled with pus-corpuscles and large epithelioid cells, which are considered by many authors to be the offspring of the alveolar epithelium. The alveolar walls are also infiltrated. This finally results in the destruction of the cheesy and necrotic tissue, and consequently in the formation of cavities. At other times the neighboring nodules run together, and the tubercular infiltration thus extends, giving rise to a diffuse caseous pneumonia. These processes may all be readily recognized by the naked eye. The earlier stages of atelectasis and infiltration correspond to the jelly-like, gray coloring seen in the so-called gelatinous infiltration of Laennec, and the transition to caseation is recognized by the eye from the yellowish color.

Although all the processes thus far described are destructive in their nature, changes are also found in the lungs, in tuberculosis, which seem to have a tendency toward circumscribing the disease and toward healing. Prominent among these

are the chronic interstitial processes. We meet with the formation of new connective tissue, partly about the tubercular infiltration, but especially where there is already destruction of tissue, and this leads to contraction and the formation of a firm cicatrix. The encapsulated cheesy masses may then be in part reabsorbed; in part they undergo calcification. The possibility of such a halt in the tuberculous process depends, however, upon certain conditions. The tuberculous new growth and its destruction must not advance too rapidly, and the new-formed tissue must not itself be destroyed before it becomes cicatrized. We see the cicatricial formation, therefore, more especially in chronic cases; we find it in places which have been affected the longest, and where the tubercular process, perhaps, has finally come to a standstill of its own accord. Macroscopically, this cicatricial connective tissue is composed of a thick, firm substance, usually pigmented—the so-called pigment induration. If the cicatricial formation follows a previous extensive destruction of the pulmonary tissue, the affected portion of the lung may thus be diminished to less than half its original bulk. Cavities and firm cicatricial tissue form the anatomical basis of such an extensive "pulmonary contraction." The cavities are either formed in the usual way from the destruction of lung tissue, or they may be simple bronchial dilatations due to the traction of the contracted tissue—bronchiectatic cavities.

The contractile changes in pulmonary tuberculosis teach us that the tubercular process is in itself capable of healing. The incurability of most cases of phthisis is due to the fact that the infectious material from every existing tubercular nodule is carried into other bronchi, and there sets up a new tuberculosis. Thus the disease is constantly extended. The original tuberculosis, which was localized in one apex only, gradually spreads to the lower portion of the lung. The infectious material is carried by coughing into the trachea, and from this point may be carried by inspiration into the other lung. This becomes diseased, and finally there is such an extensive destruction of the lungs as to make the further continuance of life impossible.

Besides the spots of specific tubercular disease, we very often find in phthisical lungs simple inflammatory processes, bronchitis, lobular catarrhal pneumonia, and sometimes even croupous pneumonia. This, of course, is rarely extensive. These changes may be partly due to the influence of the tubercle bacilli themselves in exciting inflammation, but it is, of course, easily conceivable that many other excitants of inflammation may easily settle in the secretions of the bronchi and the cavities, and lead to complicating diseases of the bronchial mucous membrane and the alveoli. Thus in pulmonary tuberculosis a local gangrene may occasionally arise. An especial importance attaches to the secondary inflammatory processes in the lungs, because they furnish a suitable spot for the subsequent invasion of the tubercle bacilli. Thus, in phthisical patients, foci of simple inflammation very frequently assume a tuberculous character.

If we consider the list of anatomical processes which are found in tuberculosis of the lungs, and which may be combined in the most manifold ways, we can understand the great diversity in the anatomical picture in different cases. Simple bronchitis, tuberculosis of the bronchial wall and tubercular peribronchitis, diffuse cheesy pneumonia, and destruction of the tubercular new growths, with the formation of cavities, on the one hand, contracting interstitial pneumonia, cicatricial formation, and pigment induration on the other—these are the comparatively simple anatomical lesions from which the whole process in its most varied forms is composed. Besides this, we often find here and there one or more miliary tubercles scattered through the lungs which are probably due very largely to an extension of the infectious material by means of the blood or lymph current.

The secondary tubercular diseases of the pleura, the bronchial glands, and other organs, will receive a special description.

#### CLINICAL HISTORY OF TUBERCULOSIS IN GENERAL AND OF PULMONARY TUBERCULOSIS IN PARTICULAR.

In judging of the various appearances in the clinical picture of tuberculosis we must especially consider the following points: The place of the first infection is of the chief importance—that is, the place where a local affection, set up by the tubercular poison, first arises. As has been said, the lungs are the organs first attacked in a large number of cases, and such cases are termed primary pulmonary tuberculosis. In other cases, the tubercular poison first fixes itself in the larynx, as in primary laryngeal tuberculosis, or it reaches the intestine, as in primary intestinal tuberculosis, or the genito-urinary organs, as in primary tuberculosis of the genito-urinary apparatus, etc. In other cases still, we apparently have to do with a primary tuberculosis of the serous membranes (*vide infra*) or of the lymph-glands, particularly the bronchial lymph-glands (*vide infra*); and finally, we very often see primary tubercular diseases of the bones and joints, to which the most part of the formerly so-called chronic scrofulous and fungous inflammations of the bones and joints belong. It is obvious that all these diseases, although identical aetiologically, must have a very different clinical appearance.

Another reason for the great variation in the course of tuberculosis is found in the fact that the extension of the local tubercular process may vary very greatly as regards time. Tuberculosis in one case may produce the most extensive destruction in both lungs in a few months or even weeks, and in another case it may remain almost quiescent for years, or advance only very slowly. We do not know fully on what these differences depend, but much is certainly due to the hygienic influences under which the patient lives. In the last instance, however, we are often led to think of individual differences of constitution, which now check and now favor the rapid extension of the disease.

A third and final reason for the differences in the course of tubercular infection is the manner of the further extension of the tubercular poison in the body. As we shall see in the description of tuberculosis in single organs, there are different ways in which tuberculosis may pass from one organ to another. Many contingencies are involved here, and we can easily comprehend how greatly the whole clinical course of the disease must be modified by the rapidity and the degree in which individual organs are affected.

After these preliminary remarks, which we have thought necessary to a right understanding of tubercular disease in general, we will pass on to the description of the clinical course of pulmonary tuberculosis.

The onset of pulmonary tuberculosis is quite slow and gradual in the majority of cases. The patient can give only an approximate idea of the time when he began to be ill. The symptoms which he notices are referred directly to the respiratory organs. The cough and its attendant expectoration are the chief things which affect him. Besides that, there is often pain in the chest, either the pleuritic stitch, or a pain in the sternal region, or pain between the shoulder-blades. The patient is also apt to complain of shortness of breath, especially on severe physical exertion.

Besides these symptoms, which point pretty directly to disease of the lungs, there are often quite striking general symptoms. The patient's emaciation is especially noticeable, which may be partly, though not wholly, explained by his loss of appetite. Besides the emaciation there is a steadily increasing pallor of the

skin. The patient also shows a general dullness, weakness, and disinclination to work. There is not infrequently a slight rise of temperature in the first stages of the disease, which causes chilliness and subjective feelings of heat. Severe night-sweats may also be noticed early.

All such general symptoms should determine the physician not to regard the mild thoracic symptoms, which are also present, as insignificant, but to think of the possibility of incipient tuberculosis. It is very important to remember that the pulmonary symptoms may be entirely subordinate to the general symptoms mentioned, and that the patient himself is apt to pay little or no attention to them. Incipient phthisis is therefore frequently diagnosticated as simple "chlorosis" or "gastric catarrh" for a long time, and is treated as such. An early and careful physical examination of the lungs and of the expectoration is the only protection against such an error.

Both the pulmonary and the general symptoms assume significance, if we have to do with a patient in whom we suspect a "tubercular predisposition." We very often meet people in whose family, either in the parents or the brothers and sisters, several cases of phthisis have occurred. They are persons who are always pale and weak, and who have previously shown a special liability to disease, particularly to disease of the respiratory organs. They have perhaps had diseases which our present theories bring into direct relation with tubercular infection. We refer to those quite frequent cases of pulmonary tuberculosis in persons who have previously suffered from "scrofulous diseases," like chronic swelling of the lymph-glands, chronic affections of the eye or ear, or fungous diseases of the bones and joints. This fact does not signify that scrofula passes into tuberculosis. It is much more probable that many scrofulous diseases are really tubercular, as has been proved by the result of inoculations in animals, and recently by the discovery of tubercle bacilli in "scrofulous" lymph-glands and in the fungous nodules in the bones and joints.

As we have said, pulmonary tuberculosis often develops in persons who have suffered before from diseases of the respiratory mucous membrane, in whom, as the expression is, the lungs have always been the *locus minoris resistentiæ*. The predisposition to tuberculosis may really perhaps coincide at times with the predisposition to other pulmonary affections; thus we see tubercular patients who have previously had several attacks of croupous pneumonia. In other cases, however, the predisposition to tuberculosis is probably caused by some disease of the respiratory mucous membrane, although sometimes these previous diseases of the respiratory organs are themselves of a tubercular nature. This is especially true of pleurisy, but we shall have to take up its relation to pulmonary tuberculosis somewhat more in detail in our description of pleurisy.

Although the first symptoms of pulmonary tuberculosis often develop in people who were not quite well before, this is true in only a part of the cases. We often see precisely the same symptoms, both the pulmonary and the general, occurring in persons who previously seemed quite well and strong. No constitution is perfectly protected against the disease. We have even seen the herculean athletes of a circus die of phthisis.

In distinction from the slow and gradual method of the development of tuberculosis which has just been described, the first symptoms in other cases may be more sudden. A definite exposure is often given as a cause, after which the first symptoms of the disease have speedily developed. It goes without saying that we must consider these harmful influences—a chilling of the body, a cold draught, over-exertion, or marked mental excitement—at most, as exciting causes.

Some cases in our own observation seem to us worthy of note, in which young people have fallen ill quite suddenly, with rather severe, general febrile symp-

toms. At first no cause for the fever could be made out, so that the diagnosis was in doubt, or the attack was even falsely regarded as typhoid or some other disease. Some time later thoracic symptoms developed, and it became possible to detect the physical signs of phthisis. Most of these cases took quite a rapidly progressive course.

In conclusion, those cases are to be mentioned in which the first signs of tuberculosis appear, not in the lungs but in the larynx. The full description of these cases has already been given in the chapter on laryngeal tuberculosis (see page 136).

The further course of pulmonary tuberculosis may vary so much that it is impossible to give a complete enumeration of all the possibilities.

In some cases it advances rapidly. We can make out the extension of the disease objectively, almost from week to week. At first the apex of one lung alone is attacked, soon after the lower lobe of the same lung, then the other lung, either at the apex first or in the lower part. Besides the pulmonary symptoms, there is quite a high fever, rapidly increasing emaciation, and general loss of strength. Death ensues in a few months. We term such cases florid phthisis, or "galloping consumption."

In other cases, however, the disease has a remarkably chronic course. Its onset is very gradual, or else, after rather an acute onset, there is a comparative cessation of all symptoms. The thoracic symptoms do not disappear, but they are only trifling, and do not disturb the patient. Physical examination of the lungs does not show any extension of the process for months. The fever which accompanies it is slight, if there be any. The patient remains quite well nourished, but in some cases there is a good deal of weakness. He feels better and worse by turns, his condition being greatly influenced by the care and nursing he receives.

Unilateral contracting phthisis especially has this comparatively favorable course (*vide supra*). The affection remains confined to one lung for a long time. The occurrence of contraction shows the slight tendency of the tubercular process to advance, and with satisfactory care the patient may remain quite well for years.

In cases, too, which have had severe symptoms for a long time, a temporary standstill of the affection may take place, or an actual improvement in all the symptoms. At other times, in cases which have made no advance for a long time, the symptoms suddenly grow worse.

There are all possible varieties between the extremes of florid phthisis and the very chronic cases which last for years. If we recall the further modifications which the course of the disease may assume if complications arise, we can appreciate the manifold character of the clinical picture of phthisis.

Most cases terminate fatally. Death ensues, either with the signs of general exhaustion, or as a result of the final failure of respiration; or it is due to the occurrence of complications, like tubercular meningitis, miliary tuberculosis, pulmonary hæmorrhage, or pneumothorax. A recovery from the tubercular process is certainly possible. The comparatively great rarity of recovery in pulmonary tuberculosis, however, is due chiefly to the possibility of the continual spread of the tubercular poison in the lungs themselves, and also in other organs. From clinical and pathological experience, however, we can not deny the possibility of definite recovery in pulmonary tuberculosis. We do not, of course, mean a *restitutio ad integrum* of the lung-tissue, but a recovery with a cessation of the tubercular process, and with the formation of a cicatrix, or contraction. Such recoveries, as we have said, are rare, and they occur only where the changes in the lungs are of limited extent. The possibility of recovery depends mainly upon the general physical constitution and upon the external circumstances of the patient.

## SPECIAL SYMPTOMS AND COMPLICATIONS.

**1. Symptoms on the Part of the Lungs.**—*Pain in the Chest.*—Extensive destruction in the lungs may exist without any feeling of pain. Many cases of phthisis are painless throughout their course. In other cases, however, the patient's chief complaint is of severe pains in the side or in the front of the chest. These are probably always due to co-existing affections of the pleura, like pleurisy, or pleuritic adhesions. In patients who suffer from severe cough, pains sometimes arise in the abdominal muscles and at the insertion of the diaphragm, due to the excessive muscular contraction. Stabbing pains between the shoulder-blades are held by some to be not wholly unimportant as a diagnostic symptom of incipient phthisis.

*Cough.*—In the majority of instances cough is one of the most distressing symptoms in phthisis, but its severity varies very much in different individuals, and at different times in the same patient. We sometimes see cases in which, in spite of advancing phthisis, cough is remarkably slight, or entirely absent. In these we usually have to do with patients who are very slightly sensitive. In cases with severe cough, it is often worst at night, but paroxysms of coughing of long duration are also apt to come on in the morning or evening hours, which are painful and very distressing, and unpleasant for the patient. The cough is usually associated with a more or less abundant expectoration, but sometimes there is chiefly a dry cough. The cough becomes very severe if the tubercular affection attacks the larynx and trachea (see laryngeal tuberculosis).

*Expectoration.*—The amount of expectoration differs very much in different cases. It is most abundant where there is extensive formation of cavities in the lungs. In such cases it is often evacuated in the morning by persistent coughing. The consistency of the great part of the sputum is muco-purulent, and it does not differ from that of simple bronchitis; in fact, a large part of the phthisical expectoration comes from the catarrhal inflammation of the bronchial mucous membrane. Another part comes from the purulent secretion of the walls of the cavities. The sputum has a characteristic tendency to roll itself together in single large lumps, into the ball-like or so-called nummular sputa. This is noticed especially where there are cavities.

The admixture of blood with the sputum is of great diagnostic and practical importance. Since no other disease so often gives rise to the presence of blood in the expectoration, coughing of blood (hæmoptysis) is almost synonymous with consumption among the laity. Little streaks of blood in the expectoration are quite frequent. They have no great significance, but, of course, they may sometimes be the precursors of severe hæmorrhages. Profuse hæmoptysis takes place when the wall of a little pulmonary vessel—almost always a branch of the pulmonary artery—is infiltrated, destroyed, and finally eroded, by the tubercular new growth. The reason why hæmoptysis is not more frequent is because the contents of the vessels usually undergo thrombosis. Severe hæmorrhages very often have their origin in the perforation of little aneurisms of the branches of the pulmonary artery, which penetrate into the interior of the cavities. In the cases of fatal hæmoptysis we frequently succeed in finding the little aneurism and its point of rupture.

Pulmonary hæmorrhages occur in all stages of phthisis. The amount of blood coughed up sometimes amounts to only one or two tablespoonfuls, sometimes to one or two pints. The blood is bright-red in color, usually quite frothy, only slightly coagulated, and partly mixed with the other constituents of the sputum. If the patient recovers from the first severe hæmoptysis, the expectoration usually contains some blood for several days. Recurrences of severe hæmorrhages are

frequent. The hæmoptysis sometimes comes on quite suddenly, often at night, without any occasion, but it may return from some definite cause, such as physical exertion, severe paroxysms of coughing, straining at stool, or mental excitement. Many cases of phthisis are characterized by a special tendency to hæmorrhage, while in many others hæmoptysis never occurs. Severe hæmoptyses are, of course, always an undesirable and dangerous complication, since they weaken the patient very much, and also depress his spirits. Many patients maintain their peculiar, careless indifference, which is almost characteristic of the disease, despite the spitting of blood. The hæmoptysis may sometimes be the direct cause of death, but, as a rule, the patients survive it. We can not make the general statement that the further course of phthisis is materially hastened by hæmoptysis. In not rare instances, however, it is observed that after a hæmoptysis the pulmonary disease extends more rapidly, the fever becomes higher and more persistent, and the general condition of the patient grows worse.

A purulent sputum intimately mixed with blood is quite frequent and characteristic in many cases of phthisis with extensive formation of cavities. This is formed in the cavities from the mixture of the purulent secretion with little capillary hæmorrhages. In this way the sputum, which is often nummular, assumes a greasy character and a reddish-brown or chocolate color.

If foetid or gangrenous processes develop in the lungs, the sputum becomes foetid. In some cases we see temporarily in phthisis the characteristic sputum of croupous pneumonia, which comes from portions of the lung attacked with pneumonia.

Microscopic examination of the sputum may show—besides the ordinary elementary forms, such as pus-corpuscles, red blood-corpuscles, pavement epithelium, drops of myeline, and sometimes, perhaps, pulmonary epithelium—two constituents which are of decided diagnostic importance: elastic fibers and tubercle bacilli.

The demonstration of elastic fibers in the expectoration permits us to decide with certainty that there is a destructive process in the lungs, and thus it usually is direct proof of tuberculosis. Elastic fibers are also found in pulmonary gangrene, and in the very rare cases of pulmonary abscess, as well as in tuberculosis, but gangrene is easily recognized by the other peculiarities of the sputum. The search for elastic fibers in the expectoration of tubercular patients demands a certain amount of practice. We are most sure to find them if we look in the sputum, when it is spread out, for little lentiform particles, which can easily be made out with the naked eye. These consist of necrotic shreds of tissue torn off from the walls of cavities. If we press one of these "kernels" under a cover-glass we find, in the midst of the granular detritus, beautifully twisted elastic fibers, which often have quite a definite alveolar arrangement (see Fig. 26). The elastic tissue is the only one spared in the general destruction. There is a special method of looking for elastic fibers, but we have found it unnecessary. The sputum is boiled in sodic hydrate dissolved in water, and we look for elastic fibers in the precipitate which then forms. We are never justified, however, in deciding that pulmonary tuberculosis is absent because we do not find elastic fibers in the sputum. Their presence is the only thing that has real diagnostic significance.

FIG. 26.—Elastic fibers.

The discovery of tubercle bacilli in the expectoration of phthisical patients is of much greater importance, and often this alone is decisive (see Fig. 27). They

FIG. 27.—Tubercle bacilli in the sputum.

were first demonstrated by Koch, but Ehrlich devised the first simple method for their discovery, which can be easily employed by any physician.

The sputum is spread in the thinnest possible film on a cover-glass, and permitted to dry on it. The best way to do this is to rub some of the sputum between two cover-glasses, and to slide one slowly off of the other. We pass the cover-glass through the gas-flame three times slowly to fix the sputum, and then, after cooling it for a little time, we let it float in the staining fluid. The latter is made in this way: One part of aniline oil and six parts of water are mixed in a test-tube, filtered, and to the filtrate, known as aniline-water, a portion of

which is placed in a watch-glass, about eight or ten drops of a concentrated alcoholic solution of methyl violet or gentian violet are added. The cover-glass on which the sputum has been placed is allowed to remain in the watch-glass as long as possible—one or two hours, or more. If it is desired to shorten the process, the staining liquid is warmed, but not to the boiling-point. The bacilli will in this case usually be stained with sufficient distinctness in as short a time as ten or fifteen minutes. When the cover-glass is taken out of the staining fluid it is immersed in a solution of one part of nitric acid in three parts of water, and in this way the preparation is almost completely bleached in a very short time. The tubercle bacilli alone have the property of retaining the stain which they have taken on, despite the action of the nitric acid. When the cover-glass is taken out of the nitric acid, it is rinsed in water, dried between two layers of blotting-paper, then stained for about a minute in a one- or two-per-cent. solution of Bismarck-brown in water, then dried, and examined in water, or, better, in Canada balsam. A dry lens of the strength of, say, objective number eight of Hartnack (330 to 440 diameters) answers perfectly for the examination. The pus-cells and any other bacteria that may be present are colored brown. The tubercle bacilli, however, are stained dark blue. Ziehl and Neelsen's staining fluid is also to be highly recommended. It is composed of one hundred parts of distilled water, five parts of carbolic-acid crystals, and one part of fuchsin. After these are mixed and filtered, ten parts of alcohol are added. A solution thus prepared lasts for quite a long while, and stains the tubercle bacilli a bright red even in a few minutes, provided warmth is employed. For bleaching the other components of the preparation, a five-per-cent. solution of sulphuric acid may be employed, and the best means of secondary staining of the pus-corpuscles is to use a watery solution of methyl blue. If a solution is made up containing fifty parts of water, thirty of alcohol, twenty of nitric acid, and as much methyl blue as the liquid will take up, the bleaching and the secondary staining may be accomplished simultaneously. This is a very practical method, which was first recommended by B. Fränkel.

The number of bacilli varies a good deal in different cases, and at different times in the same case. The more bacilli there are, the more readily can we decide that there are extensive processes of ulceration. We can found no definite prognostic conclusions upon the behavior of the bacilli, but their presence is of the greatest significance in a diagnostic point of view, especially as they can be

found upon careful examination in incipient cases. At so early a period all the other symptoms by themselves would very often not warrant an absolute diagnosis.

*Dyspnœa*.—A marked subjective feeling of dyspnœa is a symptom which is of relatively rare occurrence in phthisis.

Many patients hardly ever complain of their breathing in spite of extensive destruction in the lungs. A patient who is much emaciated manifestly needs little oxygen, and the increased frequency of respiration, which is almost constant, can satisfy his needs. If there is a greater demand upon the respiration, a subjective feeling of dyspnœa may of course very readily occur, especially on a slight bodily exertion. In many cases, however, the patient complains of a difficulty in breathing even when quiet, especially if pleuritic pains or adhesions between the surfaces of the pleura prevent him from taking a deep breath, and in the final stages the dyspnœa may be extreme.

**2. Symptoms on Physical Examination.**—In many cases inspection gives us that general impression of the patient which we term the "phthisical habit." The special signs of this are as follows: A slender but often quite a tall frame, weak muscular development, a thin layer of fat, a pale and perhaps very delicate skin with a bluish translucence, sometimes a circumscribed "hectic" flush in the cheeks, a long and slender neck, a long and narrow thorax, small, thin hands, etc. There are, of course, many variations from this type in individual cases.

The inspection of the thorax is of special value. The phthisical or "paralytic" thorax is generally noticeable from its length, but it is narrow and flat. Unusual width of single intercostal spaces, and acuteness of the epigastric angle, are associated with a long thorax. The sternum is also long and narrow, and the sternal angle—Louis's angle—is often prominent. The supra-clavicular and infra-clavicular fossæ are sunken, the neck is wasted, and the shoulder-blades stand out from the thorax. On comparing the two halves of the body, we very likely see unilateral contractions, most frequently in the upper and anterior portion of the thorax, but also in the lower portions.

The paralytic form of thorax is very often seen in phthisis, but it may be entirely absent.

The respiration is usually somewhat accelerated, and sometimes quite markedly so in women with disease of the apices. The feminine type of high thoracic breathing is largely changed to low thoracic or diaphragmatic breathing. A unilateral impairment of respiration is of greater importance; in such a case one apex, or one side, if there be phthisis of the lower lobe, holds back in inspiration. The respiration is sometimes irregular, especially if there be pleuritic pains.

The results of percussion are, of course, entirely dependent upon the sort of anatomical changes in the lungs, and hence differ very greatly in different cases. Since the phthisical process begins in the apices in the majority of cases, our chief attention is turned to the condition of the upper portions of the lungs on percussion. Slight changes in percussion may wholly escape discovery. Only when the air contained in the lung-tissue in the part affected is replaced to a certain degree by the tubercular infiltration does the percussion-note become dull. Unilateral dullness at the apex is therefore one of the most frequent physical signs of phthisis. We can usually make it out most plainly in the upper anterior intercostal spaces first, and in incipient cases often in the supra-clavicular fossæ only, but it is also observed sometimes in the back in the supra-scapular fossæ. As the infiltration advances the dullness becomes more extensive. It frequently assumes a tympanitic quality, as a result of diminished tension or partial retraction of the lung-tissue.

The formation of cavities in tuberculosis has a great influence on the percussion-note. The dullness on percussion may thus become decidedly less, the degree

of resonance depending, of course, upon the fullness of the cavity and the character of the surrounding tissue. We often find a decided tympanitic resonance or a combination of dullness and tympany over a cavity. The different modifications of the percussion-note in cavities are given below. The "cracked-pot resonance," or buckram sound, is met with in percussing over cavities, but we also find it in many other pathological conditions.

Auscultation also gives no special pathognomonic signs of phthisis. Varying with the character and extent of the tubercular changes, abnormal respiratory sounds and adventitious sounds are heard in place of the normal vesicular murmur. With slighter changes the vesicular breathing is merely modified; it seems remarkably diminished or interrupted, or sometimes exaggerated, with prolonged expiration. When the infiltration of the lungs increases, we find bronchial respiration in place of the vesicular breathing; but, on the other hand, the formation of a cavity is a frequent cause of bronchial respiration.

The most constant auscultatory signs of phthisis, and the most important for diagnosis, are the different kinds of râles, which are due to the accumulation of the secretion in the bronchi or in the cavities. They are heard at one apex only, or over a larger space, according to the extent of the affection.

**PHYSICAL DIAGNOSIS OF INCIPIENT PHTHISIS.**—On account of the importance of the diagnosis of incipient phthisis, we will here mention connectedly the physical signs which are chiefly met with in it. The auscultatory signs in the beginning of the disease are generally more certain and easier to recognize than those from percussion. He who lays too much weight on the so-called "slight dullness at the apex" will often make a false diagnosis. We will mention particularly the following symptoms: 1. Constant and evident diminution of the respiratory murmur at one apex, especially if it is associated with marked deficiency of the respiratory movement on the affected side. In some cases the respiratory murmur on the diseased side is not weaker, but it has a more indefinite and harsher character; or again it may be rude, sharp, and "puerile." 2. Markedly interrupted respiration at one apex. 3. A prolonged expiratory murmur, which has a harsh character. 4. The discovery of dry rhonchi or moist râles at one apex is most important, since we know by experience that "apex catarrhs" are, as a rule, tubercular. 5. Definite dullness, apparent on repeated examinations, or tympanitic dullness at one apex. 6. Evident contraction at one apex, as revealed by inspection or percussion above the clavicles. 7. Some authors lay stress upon a systolic murmur in the subclavian artery, especially loud on expiration. This may occur in the beginning of phthisis, if the caliber of the vessel is narrowed by processes of contraction in the neighboring apex, but this symptom is neither frequent nor of great practical importance.

The chief rule in the diagnosis of incipient phthisis must be held to be this—not to give a definite opinion until repeated examinations have been made. The other portions of the lungs are to be carefully examined as well as the apices, since in not very rare cases tuberculosis may begin in the lower lobes. We must always consider the patient's general symptoms as well as the physical signs.

**SYMPTOMS OF CAVITIES.**—The diagnosis of a cavity in the lungs by means of the physical signs is often very difficult. We may mention as the chief symptoms of a cavity: 1. Loud bronchial respiration, perhaps of an amphoric character, in places where the percussion-note is only slightly or not at all dull. Such a condition means that the bronchial respiration is not due to an infiltration of lung-tissue. Bronchial respiration, however, may of course be heard over cavities which are surrounded by thickened lung-tissue, and hence give dullness on percussion. 2. The so-called metamorphosing respiration, which begins as vesicular

and suddenly becomes bronchial, is heard especially over cavities, and hence has a diagnostic value. 3. The different kinds of "changes in the percussion-note" over cavities are important signs. Wintrich's change in pitch is when the tympanitic resonance, which is obtained over the cavity, becomes, on opening the mouth, more decidedly tympanitic, louder, and especially much higher. The respiratory change of pitch of Friedreich usually consists of a higher pitch on inspiration, but here there are numerous variations. Gerhardt's change of pitch (Weil) consists in a change of the tympanitic resonance when the patient changes his position, the pitch usually being higher when the patient sits up than when he is lying down.\* 4. Loud, bubbling râles are one of the most frequent signs of a cavity. They are definite indications of the occurrence of râles in a larger space than is normally present in the apices of the lungs.

**CONTRACTION OF THE LUNGS [FIBROID PHTHISIS].**—Unilateral contraction of the lungs, more frequent on the left than on the right, is a form of tuberculosis which is made apparent both by special physical signs and also by certain clinical peculiarities. It is usually recognized at once by inspection of the thorax, one side of the thorax being remarkably retracted. The upper anterior portions of the thorax; and, in all cases of a high degree of disease, the lower lateral and posterior portions, are much less tense than the corresponding parts on the other healthy side. The fossæ and intercostal spaces on the affected side are deeper, the shoulder-blade is drawn nearer the vertebral column, and the latter is even sometimes drawn over to the contracted side (scoliosis). The resonance is diminished to a greater or less degree, over the affected side, which either lags behind or remains almost wholly at rest on respiration. The respiratory murmur is quite loud, and bronchial; and we also hear many râles, which are usually bubbling. Anatomically, we have to do with a marked process of contraction of the interstitial connective tissue in the lungs, which is almost always associated with extensive formation of cavities, partly of an ulcerative, partly of a bronchiectatic character. The pleura is involved in the process almost without exception, but almost always secondarily; it is also thickened and contracted. If the pleuritic thickening is marked, the respiratory murmur and the vocal fremitus are decidedly weakened.

The influence of the contraction on the neighboring organs is very decided, and usually it is easy to discover. The heart especially, whose external pericardium is in most cases very adherent to the pleura, is drawn well over to the side of the contraction. The apex-beat and the cardiac dullness are correspondingly displaced. With left-sided contraction the heart may be drawn over to the line of the left axilla, and with right-sided contraction it may be drawn to the median line, or even to the right of the sternum. With contraction of the left upper lobe the anterior surface of the heart comes into immediate contact with the anterior chest-wall over a larger area than normal. We therefore see the motions of the heart over an abnormal extent, and we can often feel very plainly in the second left intercostal space the pulsation and the closure of the valves in diastole of the pulmonary artery. The upward traction of the diaphragm may be recognized by the position of the liver, or, in left-sided contraction, by the increase of the "semilunar" tympanitic space on the left. We usually find the sound lung on the other side quite emphysematous, as shown by the downward displacement of the lower boundary of the lung, and also by the drawing over of the anterior median edge of the lung to the contracted side. In a part of the cases we can make out by percussion the development of consecutive dilatation and hypertrophy of the right ventricle.

\* Fuller details of the significance of the different changes in the pitch are found in Weil's "Handbuch der topographischen Percussion." Leipzig: Vogel, 1850.

These are the chief physical signs of the so-called unilateral form of chronic pulmonary contraction. We would add here a few clinical remarks. The cases often, but of course not always, run a very chronic course, lasting for years. The general condition and the nutrition of the patient may thus remain comparatively undisturbed for a long time. The patient looks somewhat pale and cyanotic, yet he is so well nourished as to present a very marked contrast to the appearance of the ordinary cases of phthisis. The appetite remains good, the fever is entirely absent, or else a slight degree of fever may be at times discovered by careful examination. The cough and expectoration, too, though often very severe, are at other times very slight, especially when the patient has good care and nourishment. We need not wonder, then, that many physicians do not consider that these cases have anything to do with phthisis—"consumption"; and yet we are convinced by many clinical and anatomical observations that, etiologically, they are in by far the greatest part tubercular. They represent a very slow form of tuberculosis, which has time to develop interstitial processes which lead to contraction—that is, to local healing. If such cases come to autopsy, their tubercular character is usually definitely confirmed. We find undoubted tubercular lesions in the other lung and also in the remaining organs—e. g., the intestines. Furthermore, sudden changes for the worse may occur in every "pulmonary contraction," even those cases which seem favorable; the other lung may become highly tubercular, a miliary tuberculosis or a tubercular meningitis may develop, etc. On the whole, however, the slow course of this form of chronic tuberculosis is characteristic and of practical significance, and its prognosis is therefore comparatively favorable.

We can not absolutely deny that a non-tubercular unilateral contraction of the lung may occur. As a result of foetid bronchitis and pulmonary gangrene, processes of contraction develop, which are associated with the formation of bronchiectases, and certainly have nothing to do with tuberculosis. In rare cases also croupous pneumonia is followed by unilateral contraction of the lung; and finally there is a rare and by no means satisfactorily investigated form of unilateral chronic interstitial pneumonia, with contraction, often associated with the formation of bronchiectases. The differential diagnosis of these conditions from tuberculous contraction rests in part upon the clinical history, but mainly upon the absence of tubercle bacilli in the expectoration.

In conclusion, we must mention that there are very many transitional forms between pulmonary contraction and the other varieties of pulmonary tuberculosis. We find more or less extensive processes of contraction in one apex in most cases of phthisis.

**DISSEMINATED PULMONARY TUBERCULOSIS.**—There is a form of pulmonary tuberculosis which it is very hard to make out on physical examination. In this we have to do with numerous peribronchial nodules disseminated over the whole lung. As there is still a good deal of normal tissue, containing air, between these nodules, percussion affords no dullness, and auscultation gives at most diffuse rhonchi; hence this form is often confused with chronic bronchitis or pulmonary emphysema. The diagnosis can seldom be made from the physical signs, but only from the other symptoms, such as fever, emaciation, striking pallor of the skin, and the sputum.

This form of phthisis sometimes runs a chronic course, but usually it is quite rapid. It occurs in elderly people, and also in children. Many forms of "disseminated, coarse granular" tuberculosis are transitional forms between this and genuine acute miliary tuberculosis.

**3. General Symptoms in Pulmonary Tuberculosis.**—In the description of the general course of pulmonary tuberculosis we have already mentioned the value of the general symptoms in diagnosis and prognosis.

*Fever.*—Only a few cases of phthisis run their course entirely without fever, but it may be absent for a time, even for weeks and months. This is especially the case in the very chronic forms, like unilateral contraction. The more carefully we take the temperature, the more frequently shall we find a slight evening rise of temperature up to  $100^{\circ}$  or  $101^{\circ}$  ( $38^{\circ}$ – $38.5^{\circ}$  C.), or at least between  $99^{\circ}$  and  $100^{\circ}$  ( $37.5^{\circ}$ – $38^{\circ}$  C.), even at times when the patient is doing favorably. Such subfebrile conditions may last a long time, but many cases of phthisis are associated with high fever.

The fever in tuberculosis is generally noticeable from its very monotonous character. For months the temperature curve may be like this: in the morning a normal or approximately normal temperature, and at evening a rise to  $103^{\circ}$  or  $104^{\circ}$  ( $39^{\circ}$ – $40^{\circ}$  C.), rarely higher. The fever in phthisis, then, shows a decidedly intermitting or remitting character, the so-called "hectic fever."

More rarely we see very irregular temperature curves, where elevations of temperature, which last a shorter or a longer time, alternate in an irregular fashion with periods that are free from fever. It often happens that toward the end of the disease, when the general weakness increases, the curve, that previously was regular in its intermissions, becomes irregular. The intermissions then become deeper, and we often see genuine temperatures of collapse,  $94^{\circ}$  to  $92^{\circ}$  ( $35^{\circ}$ – $34^{\circ}$  C.). At other times the fever may temporarily assume a more continuous character, probably from an increase of the tubercular process. In some cases with an acute onset (*vide supra*) we have also seen, at the beginning of the disease, quite a high and approximately continuous fever, which later went over gradually to the ordinary hectic.

We must probably look for the cause of the fever not in the tuberculosis itself, but in the absorption of septic substances from the decomposition of the secretion of the bronchi and cavities.

In general, it may be said that continuous fever points to an advance, complete absence of fever, on the other hand, to a halt (at least a temporary one), of the tuberculous process; hence is evident the great prognostic importance of the temperature in pulmonary tuberculosis.

*Emaciation.*—The great emaciation of the patient is very striking in most cases of phthisis. The muscular system and the fatty tissue are affected in equal degree. The soft parts of the thorax are often especially involved. The emaciation is due in part to the patient's loss of appetite, and to the small amount of food which he takes in consequence thereof, but the chief cause lies in the persistent fever and the increased metamorphosis of tissue. Quite a high degree of emaciation, however, may appear in the beginning of the disease with no fever. This we are wont to ascribe to the "general illness," but the special cause of it is unknown. Under favorable external conditions phthisical patients may make quite a decided gain in weight, especially at the times when they are free from fever. In very chronic cases, which run their course from the first without fever, the nutrition of the patient may remain good for a long time. Toward the end of the disease emaciation sometimes reaches its highest degree, and many phthisical patients die "wasted to a skeleton" in the true sense of the word.

*Anæmia—Color of the Skin.*—In most cases anæmia appears in the course of the disease, which can be recognized by the pale and sallow color of the skin and the visible mucous membranes. The anæmia only rarely reaches that degree of peculiar waxy pallor that is found in idiopathic pernicious anæmia. The existence of the anæmia is also the reason why the phthisical patient does not look cyanotic, in spite of the respiratory disturbance. In the more chronic forms, where the general nutrition suffers less, we often see a cyanotic coloring of the lips and cheeks. Sometimes the skin of phthisical patients assumes a dirty, dusky

hue. We have already spoken of the circumscribed "hectic flush of the cheeks" seen with the fever.

*General Weakness—Night-Sweats—Nervous Disturbances.*—We need not say that the general emaciation and anaemia are accompanied by a marked decline in the patient's power of endurance. He finally becomes so helpless that he can scarcely move alone in the bed.

The tendency which very many patients have to severe night-sweats is not wholly explained. It may have some connection with the fall from the evening febrile temperature to the morning remission, and perhaps it is due to the greater accumulation of carbonic acid in the blood from the disturbance of respiration.

The disease has remarkably little influence upon the higher nervous functions, especially those of the mind. Most patients have a perfectly clear intellect to their latest breath. We all know the contented, hopeful disposition of many patients, who do not recognize their own danger until the last stages of the disease. Occasionally the anaemia and the general disturbance of the nutrition of the brain lead to mental alterations, such as confusion, distraction, or melancholic conditions.

We find, more frequently, disturbances in the peripheral nerves and muscles. Among these are neuralgic pains, and pains of an indefinite character, which have their seat in the legs, or sometimes in the arms, especially in the ulnar region, and which may be very distressing. Marked hyperæsthesia of the skin and deeper parts is also not uncommon. The cause of such disturbances is probably often to be looked for in degenerative changes in the peripheral nerves (Vierordt and others). Well-marked multiple neuritis has been repeatedly observed in tuberculous patients (see section on nervous diseases).

We very often see an increased reaction upon direct mechanical irritation in the emaciated muscles, and great liveliness of the so called idiomuscular contractions, which is shown, for example, on percussing the pectoral muscles on the anterior wall of the chest. The phenomena grouped under the name of tendon reflexes are also much increased in phthisis.

**4. Symptoms and Complications on the Part of Other Organs.**—1. *Pleura.*—In pulmonary tuberculosis the pleura is also involved as a rule. The affection is almost always the result of a direct extension of the process from the lung to the pleura. At the autopsy, we find in the pleura a few or many miliary tubercles, besides the simple inflammatory process—tubercular pleurisy.

In many cases, in which we have to do only with an adhesive pleurisy and with pleuritic contraction, we can merely suspect the disease of the pleura, but it can not be directly made out and differentiated clinically from the pulmonary affection. In other cases we can diagnosticate a dry pleurisy in phthisis from the occurrence of the pleuritic friction-rub. The symptoms of pleurisy become more marked if there is a pleuritic effusion, which is usually readily discovered by a physical examination. The patient's pain and dyspnoea are usually much increased by such a complication. Besides a simple sero-fibrinous effusion we quite frequently find purulent and even hæmorrhagic effusions in tuberculosis of the pleura.

The formation of pneumothorax is an important complication in the pleura in phthisis. This is due to the rupture of a superficial pulmonary cavity into the pleural cavity, and the entrance of air into the latter. The different forms of pneumothorax and its symptoms will be described under diseases of the pleura.

2. *Larynx, Pharynx, and Trachea.*—The symptoms of laryngeal tuberculosis and their relation to pulmonary tuberculosis have already been given under diseases of the larynx, although there is a primary laryngeal tuberculosis, and its development to a pulmonary tuberculosis.

hue. We have already spoken of the circumscribed "hectic flush of the cheeks" seen with the fever.

The formation of pneumothorax is an important complication in the pleura in phthisis. This is due to the rupture of a superficial pulmonary cavity into the pleural cavity, and the entrance of air into the latter. The different forms of pneumothorax and its symptoms will be described under diseases of the pleura.

2. *Larynx, Pharynx, and Trachea.*—The symptoms of laryngeal tuberculosis and their relation to pulmonary tuberculosis have already been given under diseases of the larynx. We saw there that, although there is a primary laryngeal tuberculosis, most cases are secondary in their development to a pulmonary tuber-

culosis. The constant passage of tubercular sputa from the lungs, through the trachea and larynx, naturally leads to a direct infection of the mucous membrane of the parts mentioned.

The same holds true in regard to the much rarer tuberculosis of the pharynx. In some cases this may be of primary origin, but it is usually a result of re-inoculation with tuberculosis by means of the sputum, or of a direct extension of the tubercular process from the larynx to the pharynx. Tubercular ulcers of the pharynx are found most frequently on the soft palate, on the tonsils, on the root of the tongue, and on the boundary between the pharynx and the larynx; they are rare in other parts of the pharynx. In exceptional cases tubercular affections are seen in the mouth—on the tongue. The local discomforts which all these ulcers cause is usually very considerable. Disseminated miliary tubercles, too, have been repeatedly seen in the mucous membrane of the pharynx.

3. *Stomach and Intestinal Canal—Peritoneum.*—Tubercular ulcers in the mucous membrane of the stomach are exceedingly rare, but we very often notice some symptoms on the part of the stomach. Loss of appetite is a particularly common symptom in phthisis. Vomiting occurs often in phthisical patients, especially when the larynx is involved. It is usually brought on by paroxysms of coughing. Less frequently the cause of the vomiting is gastric catarrh, occasioned by the irritation of the phthisical sputa which have been swallowed; but in some cases the gastric symptoms depend upon the general condition, like anaemia.

Although the tubercle bacilli swallowed with the sputum hardly ever infect the stomach, probably from the acid reaction of its contents, they very often attack the intestinal canal. In the majority of the cases of phthisis we find tubercular ulcers, either singly or in considerable numbers, in the vicinity of Bauhin's valves [the ileo-caecal valve], in the lower part of the ileum, and the upper part of the large intestine.

Intestinal tuberculosis does not always cause very marked clinical symptoms, but as a rule we find diarrhoea in patients with tubercular ulcers of the intestine. They may have three or four stools in the twenty-four hours, and even more, but the stools have nothing characteristic. We rarely see a slight admixture of pus or blood in them. Tubercle bacilli have been repeatedly discovered in the dejecta, but the search for them is rather difficult. We must call attention, however, to the fact that many patients have diarrhoea during life in whom we find at the autopsy no intestinal tuberculosis, but only a simple intestinal catarrh, or amyloid of the intestine. On the other hand, we quite frequently find at the autopsy tubercular ulcers of the intestine which during life caused no diarrhoea.

In cases of severe intestinal tuberculosis we sometimes meet with meteorism. With deep ulcers, extending to the peritoneum, we often see marked tenderness of the abdomen.

The peritoneum may be affected by the tubercular ulcers of the intestine in a twofold manner. Genuine peritonitis from perforation, with a purulent or even a sanious exudation, is quite rare, and is excited by the rupture of an ulcer and the entrance of the contents of the intestine into the abdominal cavity. An infection of the peritoneum with the tubercular poison is more frequent. This may arise from deep-seated ulcers, which do not reach actual perforation, so that we have a peritoneal tuberculosis, or a tubercular peritonitis. During life peritonitis from perforation and that from tuberculosis are not always to be distinguished. We must also mention that simple ascitic fluid is sometimes found in the abdominal cavity in phthisis, which may lead to a false diagnosis of peritoneal tuberculosis.

Another way in which we may have a peritoneal tuberculosis in the course of

phthisis is from the extension of the process in a tubercular pleurisy, through the diaphragm to the peritoneum.

4. *Liver and Spleen.*—We very often find a few or even many tubercles in the liver in phthisis, but they have no clinical significance. The liver is almost always infected with the tubercular poison from tubercular ulcers in the intestines, from which the poison passes to the branches of the portal vein and then to the liver. Fatty liver and amyloid or lardaceous liver are more important clinical changes. We can sometimes recognize the former by making out on physical examination the increase in the size of the organ, and by feeling its characteristic blunt lower edge.

Amyloid liver is almost always associated with the development of amyloid in other organs. In marked cases the liver is evidently enlarged, and its firm, sharp lower edge, and often its dense anterior surface, may usually be plainly felt.

Miliary tubercles or single large tubercular nodules in the spleen have a pathological interest only. Great splenic enlargement is found in amyloid degeneration.

5. *Kidneys, Urinary Passages, and Sexual Organs.*—The presence of miliary tubercles in the kidneys is the first change in them to be mentioned, but it has no clinical significance. Extensive tuberculosis of the genito-urinary apparatus, however, may produce marked symptoms, like pyuria, which will be described later. In regard to the symptoms of amyloid kidney, which may develop in the course of phthisis in connection with amyloid disease in other organs, we will refer to the section on renal diseases.

Genuine cases of nephritis, both acute and chronic, are also found quite frequently in phthisis, usually combined with amyloid disease. These can not escape notice if the urine is carefully examined. Cases of genuine amyloid kidney of moderate severity are seen, however, in which the urine remains normal, or at any rate free from albumen.

6. *Circulatory Organs.*—Not only is the frequency of the pulse increased in many patients in proportion to the existing fever, but even where there is no fever we often find it accelerated. The greater or less increase of the pulse, which readily comes on from comparatively trifling external causes, is especially noteworthy. It may be seen after slight physical exertion, or upon mental excitement, as during the physician's visit.

Anatomical changes in the heart are rare, except that it is often remarkably small and flaccid. Moderate fatty degeneration of the heart, slight endocarditis of the valves, or occasional tubercles in the heart, cause no symptoms. The occurrence of tubercular pericarditis, however, is important. This almost always arises from the extension of the tubercular process from the adjacent pleura, but in exceptional cases pericarditis has been seen as a result of rupture of a pulmonary cavity into the pericardium.

7. *Lymph-glands.*—The lymph-glands are a favorite seat for tubercular changes. We have stated above that the so-called scrofulous, cheesy lymph-glands, which are seen chiefly in the neck and the axillæ, are affected with tubercle in the majority of cases. The tubercular infection probably develops here from slight injuries and excoriations of the skin, by which the bacilli enter the body and reach the neighboring glands by means of the lymph-current. In other cases the infection perhaps comes from the mucous membrane of the pharynx. In tuberculosis of internal organs, too, we very often find the corresponding lymph-glands enlarged and more or less cheesy. The bronchial lymph-glands are swollen as a result of pulmonary tuberculosis, the mesenteric and retroperitoneal glands as a result of intestinal tuberculosis. The tuberculosis of the bronchial lymph-glands is of especial importance in children. Indeed, the tubercular

virus which has gained access to the lungs may apparently reach the bronchial glands by means of the lymph-channels even without affecting the lungs themselves, and occasion a tuberculous disease of the glands. Glands thus diseased break down and discharge into the lungs, and in this way generate a secondary pulmonary tuberculosis. This is one reason why the pulmonary tuberculosis of children so often begins not in the apex but in the middle and lower portion of the lung.

Pressure from the enlarged glands may affect the air-passages, the branches of the pulmonary artery, the veins, the recurrent nerve, and even the aorta. Perforation of the cheesy bronchial glands into the œsophagus, the blood-vessels, etc., has also been observed. Tuberculosis of the bronchial glands in children does not present any definite type of disease, however, and, although we may sometimes suspect it when there is pulmonary tuberculosis, we can only rarely diagnosticate it with certainty.

8. *Nervous System*.—We have already mentioned various nervous symptoms in the description of the general symptoms. We must also add that tubercular meningitis is seen in the course of phthisis (see page 702), and also that large solitary tubercles may occasionally develop in the central nervous system (see page 749).

9. *Skin*.—We have spoken of the great tendency which many patients have to severe sweats, especially at night. The frequent appearance of pityriasis versicolor, especially on the skin over the thorax, is also worthy of note. We often see moderate œdema of the legs and ankles, which is due to weakness of the heart. More marked œdema of one leg sometimes arises from thrombosis of the femoral vein. We must also mention here, in conclusion, the specific tubercular disease of the skin—lupus. This occurs alone, as a rule, without a co-existing pulmonary tuberculosis; but, on the other hand, the old term "scrofulous lupus" had reference to the fact that we often find other tubercular affections in lupus besides the disease of the skin. Thus it does not seem strange that lupus and phthisis have been repeatedly observed to co-exist. Cutaneous tuberculosis may develop not only in the ordinary form of lupus, but also in nodules of considerable size, or in rather extensive ulcers. Perhaps some of the cases of so-called corpse-tubercle belong to true tuberculosis. We have seen a similar tuberculous cutaneous disease in a woman who for a long time had washed the soiled handkerchiefs of a consumptive patient.

**Diagnosis.**—The diagnosis of pulmonary tuberculosis has become absolutely certain, since the discovery of the tubercle bacilli, by the demonstration of their presence in the sputum (*vide supra*). In all incipient cases, in which the other symptoms of the disease have not yet made themselves manifest, but where the suspicion of incipient phthisis has been aroused by a persistent cough, by marked pallor and emaciation, by slight hoarseness, by an evening rise of temperature, by the appearance of night-sweats, by the presence of a hereditary predisposition, and similar symptoms, the finding of tubercle bacilli in the sputum is often the sole deciding factor. We must not forget, however, that in most cases the diagnosis may be made from the other symptoms alone, and also that we can actually judge of the severity of the individual case, and of the exact extension and form of the tubercular process, only by considering the other symptoms, and especially by considering the data of the physical examination. The latter, therefore, has lost none of its importance by the discovery of the tubercle bacilli.

Confusion between phthisis and other diseases is twofold. Where the constitutional symptoms are predominant, and there are no marked pulmonary symptoms, an existing tuberculosis may be overlooked. In the beginning, especially, many cases of phthisis are considered to be merely anæmia, chronic gastric

catarrh, or simple bronchitis. If an intermitting fever appears in an early stage of phthisis, before any marked pulmonary symptoms have developed, the disease may be mistaken for malaria or the like. On the other hand, it is by no means rare to consider patients phthisical who are suffering from some entirely different affection. He who lays too great stress on the uncertain results of percussion will often make a false diagnosis. Severe latent diseases of the stomach, or certain general diseases, such as anæmia, diabetes, or chronic nephritis, may falsely be taken for phthisis. Other pulmonary affections, too, may be confounded with tuberculosis, especially chronic bronchitis, emphysema, bronchiectasis, foetid and gangrenous processes, and carcinoma of the lungs. A careful, unprejudiced, and complete examination of the patient is the only possible protection against such errors.

**Prognosis.**—In the present condition of our therapeutic knowledge the prognosis of phthisis must unfortunately still be regarded as extremely unfavorable. There can be no doubt that the tubercular process in the lungs is in itself curable, but, in all cases where we get certain objective evidence of tuberculosis, a definite extinction of the disease is very improbable, because the conditions for a further extension of the disease in the lungs are extremely favorable. In individual cases, however, with the best hygienic surroundings, circumscribed tubercular affections of the lungs have been certainly found to heal. Indeed, it is possible that recovery from pulmonary tuberculosis is more frequent than was formerly supposed; for it is precisely in the earliest stages, when the disease is still curable and tubercle bacilli have not yet been discovered, that the diagnosis is difficult and often uncertain. In advanced cases of phthisis the prognosis, of course, is almost absolutely fatal.

In individual cases the prognosis with regard to the duration of the disease is very difficult. Here we must always be mindful of the great differences in different persons, and hence we must be very cautious in expressing an opinion. How many patients with phthisis give us the impression on the first examination that they can not live a fortnight longer, and later on we see the disease lasting for many months, most of the symptoms improving, and the patient recovering again! In other cases, on the contrary, we think we have to do with an incipient case, and give great encouragement—and the patient dies in a few weeks with florid phthisis. Even disregarding the constant possibility of an unforeseen fatal hæmoptysis, pneumothorax, or tubercular meningitis, a conjecture as to the duration of the disease is, therefore, very uncertain in most cases which have not yet reached the last stage, and should be made only after long observation of the patient. Very much, of course, depends upon the circumstances of the patient, and upon the possibility of good care, suitable food, and good air.

Of the single factors which influence the prognosis, our chief attention must be paid to the general nutrition, the patient's weight, the extent of the pulmonary affection, the fever, and certain complications, especially laryngeal and intestinal tuberculosis. We need not repeat the special points which relate to these.

[Flint, especially, has called attention to the fact that phthisis is sometimes self-limited; that recovery or arrest takes place without any special treatment, and in spite of relatively unfavorable surroundings. The clinical evidence is greatly strengthened by the frequency with which, after death from any cause, the remains of an old phthisical affection are found.

In 1857, 39·50 deaths from consumption were returned in the State of Massachusetts for each ten thousand of the population; in 1883, 29·90. This decrease is too large to credit to greater accuracy in diagnosis and to the transference of consumptives to other States, and is mainly attributable to the prevention of phthisis by improved hygiene. Still, it seems fair to carry some of the improve-

ment to the account of the arrest and cure of actually developed disease through early diagnosis and more rational treatment, hygienic as well as medicinal.]

**Treatment.**—1. *Prophylaxis.*—The question of what prophylactic measures may effectually prevent the extension of the disease has entered upon a new stage since our definite knowledge as to the infectious nature of tuberculosis. We can no longer doubt the contagious character of phthisis, in support of which isolated examples were previously brought forward. Even if, according to all experience, the danger of contagion is not very great, still it is foolish to ignore it entirely. We must therefore call the attention of the relatives of phthisical patients to the possibility of this danger, and we should not permit the children of such patients to be uselessly exposed to it. We should take satisfactory precautions for isolation, and also for disinfection of the sputum, which can best be done by a strong solution of carbolic acid. The future will teach us whether many evils may not be averted by such measures, although now these measures are greatly neglected.

The "prophylaxis" at present employed is almost exclusively confined to hardening and strengthening the threatened individual as much as possible. We should try to strengthen the bodies of children of a weak habit, with "scrofulous" symptoms, and children from families in which cases of tuberculosis have already occurred, and thus to arm them against the enemy that threatens them. Good food, fresh air, and a diminution of the sensitiveness of the body by cold sponging and cold baths—these are the factors whose favorable influence is generally recognized.

The removal of certain foci of tubercular disease, already existing, from the body may prove of great prophylactic importance. We refer to the timely treatment or extirpation of scrofulous—that is, tubercular—swellings of the lymph-glands, healing or resection of tubercular bones and joints, etc. Although in individual cases we can of course never know whether the part removed is the sole focus of disease in the body, still we are undoubtedly justified in trying to remove at least one possible source of some later general infection. A fuller discussion of this important point must be left to the works on surgery.

2. *Treatment.*—We do not yet know any actual treatment, corresponding to the causal indication, whose point of attack is aimed directly against the tubercular poison. The inhalations employed with this idea, containing antiseptic substances, like carbolic acid, benzoate of sodium, and lately iodoform, have so far all proved unsatisfactory, chiefly because the substances inhaled have not reached the bronchi in sufficient amount. Inhalations of iodoform, made by a special apparatus invented by Küssner, have been the most successful in tuberculosis of the larynx. We have already spoken of inhalations with astringents and narcotics.

We must make especial mention of arsenic among the internal remedies to which a specific action in tuberculosis has been attributed. Our own experiments, which were suggested by quite a number which were made by Büchner, have in general given no favorable result. In some cases, however, the remedy seems to have a marked therapeutic action, so that we are always justified in trying arsenic in incipient cases, the more especially since it has lately been observed to have a favorable influence in other tubercular affections, like tuberculosis of the lymph-glands, caries, and lupus. It is better not to prescribe arsenic in solution, but in pills of a twentieth of a grain (grm. 0.003) of arsenious acid, giving two or three a day, and later four or five if possible, always after eating. Good results can be obtained only after using the remedy for at least some months. Another internal remedy which has been much talked about of late years is creasote. It may be given in pills, or combined with cod-liver oil, as in the following formula:

R Creasoti.....	gr. xv (grm. 1) ;
Olei morrhue.....	℥ iij 3 ijs. (grm. 100) ;
Olei menthæ piperitæ.....	gtt. 2. M.

Three or four teaspoonfuls daily.

Or it may be given in gelatine capsules, which usually contain five sixths of a grain of creasote (0.05) combined with a third of a grain of balsam of tolu (0.02). The patient should take six to twelve, or even more, of these capsules a day. Creasote may also be administered in milk. A certain improvement of the symptoms under the use of creasote, especially with regard to cough and expectoration, can not be denied. The exaggerated expectations which many physicians cherished concerning this remedy will scarcely, however, be fulfilled.

The hygienic and symptomatic treatment of phthisis is more important than the remedies so far mentioned.

The hygienic treatment, in the broadest sense of the word, aims, on the one hand, to increase the power of resistance of the body to the disease, and, on the other, to put the body under conditions which we know can combat the further extension of the disease. We try to aid, so far as possible, the process of spontaneous recovery in phthisis. First to be mentioned here is the diet of the patient, which must be as nutritious and abundant as possible. Meat, milk, eggs, farinaceous food, and butter are to be used chiefly, special care being taken that the body gets hydrocarbons and fat in sufficient amount, as well as plenty of albumen. Many of the special "cures" for phthisis have their only value in the fact that in these places the patient takes a large amount of easily assimilated nutriment, like milk, and also koumyss—which is, properly speaking, mare's milk fermented in a peculiar fashion, although with us it is artificially made from cow's milk—and also kefir, which is similar to koumyss. French physicians have lately brought forward forced feeding as a special "method" of treating consumption. It consists in giving the largest possible amounts of nourishment (pulverized meat and the like), and sometimes the food is even poured down through a stomach-tube. In ordering milk-cures we must not forget that milk soon becomes repugnant to many patients, and then it can no longer be taken in sufficient amount. In such cases we sometimes succeed in making the milk palatable to the patient by adding common salt, cognac, or coffee. It is also a good way to have an infusion of tea or coffee made with hot milk. Many patients prefer this to pure milk. As regards alcohol, we should chiefly prescribe those forms of malt liquor which are relatively rich in nutriment—e. g., porter. Small amounts of good wine may aid in improving the appetite and the general condition. Many physicians indeed believe that the stronger alcoholic beverages, such as brandy and the like, are of special benefit in the treatment of consumption, but we doubt it. Cod-liver oil, two to four tablespoonfuls a day, is a prescription which furthers the patient's nutrition, and, if it be well borne, it may be of distinct service, especially in emaciated patients. Still, we believe that one may obtain the same success by the regular daily administration of several tablespoonfuls of pure fresh cream.

We must also pay attention to the patient's manner of living, as well as care for his nutrition. Here we must endeavor, on the one hand, to remove all the injurious influences connected with his occupation, like staying in badly ventilated counting-rooms and work-shops, inhaling dust, or excessive speaking, and, on the other hand, must give him such directions as will have a favorable action on the whole body, and especially on the respiratory organs—the enjoyment of good air, free from dust, sponging the chest with cold water, and baths; but since we often can not satisfy all these demands under the patient's ordinary household conditions, it has long been the custom to send patients with thoracic diseases to

certain special health-resorts, where the conditions for a prescribed manner of living may be fulfilled more completely than at home. On this depends the so-called climatic treatment of phthisis. Many physicians assert that certain climatic factors, like temperature, moisture, and atmospheric pressure, exert a specific therapeutic influence; but this view does not seem very probable.

In regard to the choice of a temporary resort for the summer, in many cases we must content ourselves with recommending a country residence for the patient, in a region as healthy as possible, protected, dry, and well wooded, paying attention at the same time to the character of the board and lodging there. A good country boarding-place may do just as well as many expensive health-resorts. We may mention in particular, among the special health-resorts, springs, and places for inhalations in Germany, (1) the acidulous saline waters at Ems, Gleichenberg, Neuenahr, Obersalzbrunn, Reinerz, and others; (2) the chloride-of-sodium waters at Reichenhall, Salzgungen, Soden, and others; (3) the springs containing the earthy salts at Inselbad, Lippspringe, and Weissenburg. The favorable influence of these baths is best seen in cases where there is anorexia or other gastric disturbance. Besides these we may also mention some of the well-known high climatic health-resorts in the Alps: Aussee, Beatenberg, Berchtesgaden, Engelberg, Gmunden, Heiden, St. Moritz, Seelisberg, and others; and in the Black Forest: Badenweiler, St. Blasien, Rippoldsau, and others.

The choice of a winter health-resort is, under some circumstances, of still greater importance, since the colder season with us brings with it many dangers for the patient. The first to be mentioned here are the high health-resorts, where the weather is usually clear and sunny. Among these Davos enjoys the greatest reputation. This place is especially suited for patients who are still quite strong and free from fever, and who do not suffer from laryngeal symptoms. Among the winter health-resorts in Germany we must mention first Görbersdorf, and also St. Blasien. The southern climate is better for delicate, "erethistic" patients, and also for those with laryngeal affections. Of course only the very distant health-resorts in Algiers, Egypt, Malta, and the much-praised Madeira, can furnish a certain guarantee of constant mild weather. The Sicilian health-resorts (Catania and Palermo), and also Ajaccio and Pau, afford favorable climatic conditions; while the health-resorts of the Riviera (see p. 153), Meran, Areo, Lugano, and Montreux, are much more uncertain in this respect, and therefore are to be used merely as stopping-places by the way during the spring and autumn months.

We can not go into a full description here of all the health-resorts mentioned. We can not omit, however, calling special attention to the fact that we should always ask ourselves, in choosing a health-resort, whether the expense and inconvenience thus imposed upon the patient can be balanced by the possible benefit. The earlier the stage of the disease and the better the general condition of the patient, the more will his physician be justified in urging him to make every sacrifice in order to regain his health. It is blameworthy, from a professional and humane stand-point, to send patients in the last stages of phthisis among strangers, to die far from their home and relatives. For severe cases, when we wish to send them from home, the special institutions are the only suitable places, where the patient may at least be under the constant care and attention of a physician. Especial asylums for lung patients are Falkenstein on the Taunus, Görbersdorf, Inselbad at Paderborn, and Reiboldsgrün.

[Our own health-resorts for consumptives are too well known to demand extensive consideration here. The prime object is to secure for the patient a pure air, with such climatic conditions that he can pass the largest amount of time out of doors, at the same time that within doors his comfort is provided for, and a sufficiency of suitable and well-cooked food is attainable. In Colorado, New

Mexico, and California, large numbers of former consumptives are leading active lives. Florida, Aiken, Thomasville, Asheville, and some other southern resorts, are good winter asylums for many cases, but patients should not return to New England before June 1st. An out-door life in the Maine or Adirondack woods during the warmer months is highly to be recommended for early and otherwise suitable cases. Saranac, N. Y., affords every comfort during the colder months, combined with the very best medical attendance, and many people do well there. A relative disadvantage under which nearly all American health-resorts labor, as compared with those of Europe, consists in the greater difficulty in providing occupation and thus securing a mental attitude most favorable to recovery. In general, the northern sea-board is much less favorable than the interior, and early cases often do well during the winter removed from the dampness of the coast, with its alternations of freezing and thawing. A change of climate is a very important step, and should receive the most careful consideration of the physician—the circumstances of the patient, the stage and character of his disease, his tastes, etc., being carefully weighed before a decision is reached.]

We must also state that, in incipient cases, a residence by the sea, or a long sea-voyage, may sometimes be of great help. We have ourselves known several young physicians who have become ship-surgeons on account of incipient phthisis, and who have returned from the voyage much stronger, and some of them apparently entirely well.

The symptomatic treatment of phthisis is directed in the first place against the pulmonary symptoms. We use much the same remedies to help the cough as in chronic bronchitis. We try inhalations with a solution of common salt, or of the alkaline carbonates, or, where there is much secretion, with solutions of tannin and the balsams, like turpentine, or balsam of Peru. Where there is severe, spasmodic cough, inhalations with narcotic solutions sometimes give some relief, such as cherry-laurel water, opium, or bromide of potassium. It is doubtful whether the inhalation of nitrogen, recommended by many physicians, has any real therapeutic value. Pneumatic treatment, by inhalations of compressed air, may sometimes give good results in cases of incipient phthisis.

Morphine stands first among the drugs employed to check the cough. We should be cautious and sparing in its use at first, but it is an indispensable remedy in severe and hopeless cases. It relieves the irritation of coughing, the pain and the oppression in the chest, and at least gives the patient for a time the desired sleep. In chronic cases, with moderately severe symptoms, we may use for a long time the milder narcotics with advantage, like extract of hyoscyamus (extracti hyoscyami 1, aquæ lauro-cerasi 20, fifteen to twenty drops every two hours), one to three grains (grm. 0.05–0.20) of lactucarium in powder, or half a grain to a grain (grm. 0.03–0.05) of extract of belladonna in powder.\*

If the patient complains of difficulty in loosening the expectoration, we prescribe expectorants, the action of which often fails to meet our desires, but which can not be dispensed with in practice. The expectorants most frequently used are carbonate of ammonia, ipecacuanha, apomorphine, and sulphuret of antimony.† We very often combine expectorants with narcotics, as in Dover's powder.

If severe pain in the chest comes on, we often use local applications: mustard plasters, warm poultices and cold compresses, painting with iodine, or embrocations of chloroform. Narcotics, like morphine, are indispensable in severe dyspœna, which usually occurs only in the last stages of the disease or as a result of pneumothorax.

\* Extractum belladonnæ, U. S. P., is about twice the strength of the German preparation.—TRANS.

† We should use tartar emetic instead of the sulphuret.—TRANS.

The treatment of hæmoptysis is important. As a slight admixture of blood in the expectoration often precedes a severe hæmoptysis, such an event always demands caution. The patient must keep as quiet as possible, and avoid hot drinks and alcohol. When there is a severe hæmoptysis, absolute rest in bed is especially necessary. We should avoid any careful examination of the lungs, especially any severe percussion. We should lay a flat and not too heavy ice-bag over the lung on the side from which we suspect the hæmorrhage; the cold is usually well borne, but sometimes it aggravates the cough, and must then be omitted. We would also recommend swallowing bits of cracked ice. Narcotics, like morphine, are the most suitable internal remedies, since they aid the cessation of the hæmorrhage by suppressing the attacks of coughing. Among the remedies which may be employed to check the bleeding are ergotine, two or three one-grain pills (grm. 0.05) every hour; also sclerotinic acid, thirty to forty-five minims of a four-per-cent. solution subcutaneously in the twenty-four hours; and one or two grains (grm. 0.05-0.10) of acetate of lead in powder every two hours, sometimes combined with morphine. The liquor ferri chloridi (a tablespoonful of a two-per-cent. solution every one or two hours) is also recommended, but in this form it is probably entirely useless. Common salt is a remedy which sometimes seems to be of service, and which is almost always at hand. We give one or more teaspoonfuls of it in water. Acids, lemonade, and Haller's acid elixir [*mixtura sulfurica acida* (P. G.)] are favorite household remedies in hæmoptysis.

After the hæmorrhage ceases, the patient must be extremely careful for a long time, since it often recurs.

The hectic fever of phthisis is characterized by its great resistance to antipyretic remedies. It is usually utterly useless to try to combat it with large doses of quinine or salicylate of sodium. The action of antipyrine, too, is only temporary. Cold sponging of the whole body is to be highly recommended at the times of rise of temperature. It is usually well borne, and gives the patient visible relief and refreshment.

Cold sponging often diminishes the troublesome sweats in phthisis, but if this does not check them, we may often prescribe atropine to advantage, gr.  $\frac{1}{16}$  to  $\frac{1}{8}$  (grm. 0.0005-0.001) at night, but its action does not usually last very long. Lately agaricine in  $\frac{1}{2}$ - to  $\frac{1}{4}$ -grain pills (grm. 0.005-0.01) has been recommended for the night-sweats in phthisis; also picrotoxin, of which gr.  $\frac{1}{4}$  to  $\frac{1}{2}$  (grm. 0.008-0.01) is given in pill or solution at bed-time. Dusting the body with a powder of five parts of salicylic acid to ninety-five of French chalk is also a good thing. Sage tea is a favorite remedy for night-sweats—two or three cups of it cold at night—and so is milk and cognac.

If there is loss of appetite, small doses of quinine, compound tincture of cinchona, wine of cinchona, and other bitter remedies, like *tinctura amara* (P. G.), are sometimes of service. It is also frequently a good thing to prescribe a little muriatic acid, five to ten drops of the dilute acid, with the meals. It is often very hard to check diarrhœa in phthisis. Opium, combined with tannin or acetate of lead, is most effective. This subject will be discussed more fully in the chapter on intestinal tuberculosis.

We often prescribe preparations of iron, combined sometimes with quinine or arsenic (*vide supra*), in the beginning of the disease to improve the general condition and the anæmia, but, as experience shows, iron is contra-indicated in patients who are feverish or who have a tendency to hæmoptysis.

The treatment of the diseases complicating phthisis is to be found in the appropriate chapters.

## CHAPTER VII.

## ACUTE GENERAL MILIARY TUBERCULOSIS.

**Etiology.**—Acute miliary tuberculosis is a form of tuberculosis which we are justified in describing particularly because of its anatomical relations and of its peculiar clinical history. The disease is characterized anatomically by the extremely abundant development of miliary tubercles in a comparatively short time in many organs of the body. We can not liken this process to anything but an overfilling of the body with tubercle bacilli, which in some way reach the different organs at the same time, and there give rise to the eruption of tubercles. Buhl advanced the hypothesis a long time ago, that a cheesy focus could be found somewhere in the body in every case of acute miliary tuberculosis, and that the general infection of the body resulted from the absorption of these cheesy masses by the blood. Later investigations, however, have given us a much more definite explanation of the nature and manner of this general infection. Ponfick first found, in some cases of acute miliary tuberculosis, an extensive tuberculosis of the thoracic duct, with destruction of the tubercular new growth. It is easy to see how, in this way, a large amount of tubercular material could be brought directly into the circulation, from the free communication of the lymph-duct with the subclavian vein, and thus be "disseminated" through the different organs in a short time. Still more frequently, however, the tuberculosis of the large venous trunks, discovered by Weigert, especially the pulmonary veins, seems to be the starting-point for an acute general miliary tuberculosis. Usually there are tubercular lymph-glands, or sometimes other foci of tubercular disease, which unite with the wall of a neighboring vein, gradually break through it, and project into its lumen. If caseation and ulceration result in this spot, the infectious material is of course constantly washed off by the blood-current and carried away, and thus it reaches the other organs.

Since such a tubercular focus—e. g., a tubercular bronchial gland—may remain for a long time entirely without symptoms, we can understand how miliary tuberculosis may break out in an acute form in persons who previously seemed perfectly well. In other cases the patient has already suffered from some tubercular affection, until suddenly the conditions occur somewhere in the body which lead to the development of miliary tuberculosis. Thus we sometimes see it break out in a patient who has ordinary phthisis, but acute miliary tuberculosis is one of the rarities in advanced phthisis. If we find, at the autopsy of a case of acute general miliary tuberculosis, old phthisical changes in the lungs, which is by no means very common, they consist of old, partly cicatrized foci, pigment indurations, etc. We see miliary tuberculosis rather frequently as a sequel to pleuritic effusion. We have already previously called attention to the fact that in such cases the pleurisy itself is a tubercular disease. Miliary tuberculosis is also seen in people with old tubercular affections of the bones and joints, like coxitis and vertebral caries, with tubercular swellings of the lymph-glands, as in the neck and the axillæ, or with tuberculosis of the genito-urinary organs. In such cases, of course, the tubercular affection, which is discovered during life, is not always the source of the general miliary tuberculosis, but the discovery of the existence of such an affection is of the greatest significance in diagnosis, as in this way our attention is strongly directed to the possibility of a general tubercular affection.

In some cases an outbreak of miliary tuberculosis has been seen to follow other acute diseases, like typhoid, or measles.

**Pathological Anatomy.**—Except for the presence of some old tubercular affection in some organ, and except for the tuberculosis of a vein or of the thoracic

duct, which are as a rule apparent, and which have been described above, the anatomical lesion in acute miliary tuberculosis consists in the dissemination of miliary tubercles through a large number of the organs of the body. The lungs, the liver, and the spleen are constantly affected; almost as constantly the kidneys, the thyroid gland, the marrow of the bones, the heart, and the choroid; less constantly, but still quite frequently, the serous membranes and the meninges. The miliary nodules may be found in large numbers in all the organs mentioned. They may in part be easily recognized by the naked eye, and in the lungs they may be very plainly perceived by the touch. In many organs, however, especially in the liver and often in the spleen, they are hard to recognize with the naked eye, but they are easily discovered by the microscope. In regard to the histological structure of miliary tubercles, and the discovery of tubercle bacilli in them, we must refer to what has been said in the chapter on pulmonary tuberculosis, but we must also mention that, in some of the more chronic cases, some of the nodules may grow to be large tubercular foci, from the size of a lentil to that of a pea. Less developed cases of miliary tuberculosis are also found, in which only a limited number of organs are attacked, and these with less severity.

**Clinical History.**—The clinical symptoms of miliary tuberculosis depend upon two factors, the first being the general infection of the body, and the second the local tubercular affection of certain organs. Although in many organs miliary tuberculosis is entirely without symptoms, as in the liver, the kidneys, the heart, and the marrow of the bones, in two organs—the lungs, and more especially the brain—it leads to the most marked local symptoms. The miliary tuberculosis of the choroid, discovered by Cohnheim and Manz, is also without symptoms, but it can be made out with the ophthalmoscope, and is therefore of great diagnostic value.

Miliary tuberculosis affords quite different pictures, according to the predominance of one or the other of the groups of symptoms mentioned. We distinguish the four following forms:

1. *Miliary Tuberculosis, with Predominant Symptoms of General Infection: the so-called Typhoid Form.*—This form may in part greatly resemble typhoid fever. The patient, who previously seemed quite well, or in whom some local manifestation of tuberculosis was suspected, falls ill with gradually increasing general symptoms, dullness, loss of appetite, headache, and fever. Since there is no local affection to be discovered to explain the symptoms, the disease at first may well be taken for typhoid. The general condition grows worse constantly, the fever is high and continually rises, and cerebral symptoms appear. In some cases an exanthematous eruption, like roseola, may increase the resemblance to typhoid. With careful observation, however, symptoms are almost always detected later in the disease which are, to a certain degree, characteristic of miliary tuberculosis, and are due to the existence of that disease either in the lungs or in the brain. The patient's complexion assumes a peculiar pallor, and with it a definite cyanotic hue. The respiration becomes remarkably deep, and there is dyspnoea, or signs of a tubercular meningitis arise, like rigidity of the neck, loss of consciousness, disturbances in the innervation of the ocular muscles, etc., and death follows with these symptoms. These cases last from ten days to three weeks, reckoning from the beginning of the severe symptoms.

2. *Miliary Tuberculosis with Predominant Pulmonary Symptoms.*—These cases, too, may begin quite suddenly, almost like an acute croupous pneumonia, or they may develop gradually with quite a long prodromal stage. From the onset the symptoms point especially to disease of the lungs or the pleura. The patient complains of a stitch in the side, cough, and dyspnoea, and there is also usually much general weakness and fever. Later on, the pulmonary symptoms

constantly increase. The patient has extreme dyspnoea, and we can often make out an intense diffuse bronchitis on examining the lungs. The patient's face is pale, cyanotic, and anxious. Death ensues with all the signs of insufficiency of respiration. The course is usually somewhat more protracted than in the typhoid form, lasting for three or four weeks and more.

3. *Miliary Tuberculosis with Predominant Cerebral Symptoms, due to Tubercular Meningitis.*—Tuberculosis of the meninges does not belong among the regular lesions of general miliary tuberculosis. It develops in about half the cases, according to our estimation; but where it occurs it almost always gives the whole case the characteristic imprint of tubercular meningitis, by which the other symptoms are entirely concealed. The predominant symptoms are headache, fever, stupor increasing to deep coma, rigidity of the back and neck, and disturbances in the innervation of the ocular muscles. In such cases the tubercular meningitis is often the only thing diagnosticated, and the general miliary tuberculosis is not made out at all. In the cases of this sort which we have seen, a remarkable, peculiarly deep and accelerated respiration, even in the deepest coma, was the only symptom which pointed to a co-existing miliary tuberculosis of the lungs.

The symptoms of tubercular meningitis in many cases predominate in this type of the disease from the onset, but in other cases they come on during the attack and form its final period. The duration of the disease varies accordingly.

4. *Miliary Tuberculosis with a Protracted Course and Indefinite Symptoms for a Long Time—Intermitting Form.*—Besides the forms already mentioned, cases occur which usually take quite a protracted course, lasting for eight or ten weeks, and having such indefinite symptoms that a definite diagnosis is for a long time, or even throughout the disease, quite impossible. The patient complains of a number of general symptoms, such as headache and dullness, and also of thoracic symptoms, for which, however, we can find on examination no sufficient basis. There is almost always fever, usually not very high, and with a very irregular course; but we have seen a regular daily rise of temperature for a time in some cases, and attacks of fever with quite a severe chill, so that at first we thought of an irregular intermittent fever—the intermitting form. Later on the symptoms gradually increase. The apparently inexplicable loss of strength, and the patient's anæmia and emaciation, are marked, and they are important in diagnosis. Finally, either severe pulmonary symptoms or the signs of tubercular meningitis set in, to which the patient succumbs.

We must mention particularly that the four forms of miliary tuberculosis just described are only the types of the disease. In individual cases we often meet with variations and transitional forms between these types.

**Single Symptoms.**—1. *General Symptoms.*—In all cases of acute miliary tuberculosis the general condition of the patient is very serious. Most patients have a subjective feeling of severe illness, although they make little special complaint of it from the painless character of the disease. As the disease increases, there is often a marked feeling of anxiety and oppression besides the dyspnoea. There is, especially in the face, quite a peculiar pallor, characteristic of the disease, and associated with a marked cyanosis of the lips and cheeks.

2. *Fever.*—Acute miliary tuberculosis almost always runs its course with a more or less high fever, a course without fever having been observed in only a few instances. It often happens, in more protracted cases, that the temperature may be nearly normal for a time, or only slightly elevated. There is nothing characteristic or typical in the course of the fever. In the cases with typhoid symptoms the fever is usually quite high, between 103° and 105° (39.5°–40.5° C.), and rises continually, so that the temperature curve may be exactly like that of ty-

phoid. In other cases the fever is irregular and is broken by many remissions, remitting or intermitting quite regularly for some time. Death ensues with a moderately high temperature or in collapse. In cases with tubercular meningitis there is also a marked rise of temperature at the close, up to 108° (42° C.) and over.

3. *Respiratory Apparatus.*—It goes without saying that physical examination of the lungs may give no definite results. Almost every positive evidence is often wanting, and the contrast between the labored breathing and dyspnoea and the insignificance of the physical signs in the lungs is an important feature in diagnosis. Auscultation, as a rule, gives the signs of an intense bronchial catarrh; we hear rhonchi or numerous small and medium moist râles all over both lungs. The respiratory murmur itself is usually higher in pitch than normal, and in many cases it is obscure, rough, or harsh. In one of our cases there was heard, over a circumscribed area of the lung, a wholly peculiar, sharp, "lapping" sound on inspiration, which we have never heard under any other circumstances. Jürgensen describes a soft friction sound, due to miliary tuberculosis of the pleura. Percussion usually gives no objective changes. At times the resonance is rather tympanitic, or slightly dull in some places.

In some cases circumscribed pneumonic infiltration has been observed in the lungs in acute miliary tuberculosis, which may give rise to a confusion between miliary tuberculosis and croupous pneumonia, from the presence of marked dullness, crepitant râles, and bronchial respiration.

We must mention, finally, that in some of the cases physical examination of the lungs shows old changes in them, a phthisical affection of the apex, a former pleurisy, and the like. Positive evidence of such old tubercular affections may be of great diagnostic value in doubtful cases.

Dyspnoea has been repeatedly mentioned among the symptoms in the lungs. The respiration is usually very much accelerated, especially during the more advanced stage of the disease, so that we see in adults forty, sixty, and even seventy respirations a minute. The respiration is also very deep, and is sometimes associated with a loud noise. As a rule there is cough, but it is usually troublesome only in the cases with severe bronchitis. It is often very slight. The expectoration is usually scanty, and it is not characteristic. Special mention must be made of the fact that tubercle bacilli are absent in it, unless old ulcerated tubercular foci are present at the same time in the lungs.

4. *Circulatory Apparatus.*—The pulse is frequent, about 100 to 120 a minute, often weak and small, and sometimes irregular, especially if tubercular meningitis co-exists. The miliary tubercles, which anatomically are almost always to be made out in the heart, especially in the endocardium, cause no symptoms. The presence of tubercle bacilli in the blood will be mentioned below.

5. *Digestive Apparatus.*—Vomiting is frequent at the onset of the disease. The bowels are usually constipated, but in many cases there is a moderate diarrhoea. The loss of appetite, the thirst, and the dry tongue are due to the general disease and the fever. The spleen is usually somewhat, but not very much, enlarged.

6. *Nervous System.*—In many cases where the pulmonary symptoms predominate the intellect remains quite clear until the last, but in other cases cerebral symptoms, like headache, dizziness, stupor, and delirium, come on quite early, and are a part of the general infection. As has already been said, the nervous symptoms in the cases combined with tubercular meningitis become quite prominent, but in individual instances it may be hard to decide whether they are due to such a complication, or are merely severe general symptoms.

7. *Eyes.*—The ophthalmoscopic examination of the retina is of special diag-

nostic importance, since the diagnosis may be made absolutely certain by finding miliary tubercles in the choroid. A negative result, however, is never decisive against the diagnosis, since the tubercles are sometimes absent, or at least are very scanty. Their discovery is almost always difficult, and demands much practice in the method of examination. In cases with tubercular meningitis we sometimes find an optic neuritis.

**Diagnosis.**—The diagnosis of acute general miliary tuberculosis is ordinarily and justly considered very difficult. It quite often happens that at the autopsy a miliary tuberculosis is found which was not even suspected during life. It must be confessed that frequently, in such cases, we might very well have thought of acute tuberculosis. If, therefore, the possibility of acute miliary tuberculosis is brought to our attention during the patient's life, we can occasionally make quite a certain diagnosis.

The severe general condition, usually associated with fever, is most important, and for this no local cause can be found. Then come the pulmonary symptoms, especially the peculiar dyspnoea, for which there is also no adequate corresponding physical change to be discovered. It gives decided support to our suspicion if we can make out a distinct predisposition to tuberculosis, either hereditary or constitutional, or the history of a previous tubercular affection, especially pleurisy, and also chronic affections of the bones. The peculiar cyanotic pallor of the patient is very characteristic.

On these factors rests the differential diagnosis between the "typhoid" form of miliary tuberculosis and typhoid fever. Marked roseola is a distinct argument for typhoid, although it sometimes occurs in miliary tuberculosis, and so are the characteristic intestinal symptoms of typhoid, like meteorism and the peculiar stools; but we must not forget that both the roseola and the intestinal symptoms may be absent in typhoid. The course of the fever must always be considered in the differential diagnosis. It is much more frequently irregular and atypical in tuberculosis than in typhoid. Of course, the temperature curve is not an absolutely decisive factor. The occasional unequivocal evidence of the ophthalmoscopic appearances has already been mentioned.

In many cases the onset of meningeal symptoms may aid the diagnosis. Of course, if the patient is not seen until the last stages of meningitis, especially where there is an incomplete history, the diagnosis is next to impossible.

Acute tuberculosis is often confounded with severe bronchitis, especially in old people who are considered emphysematous. The very severe general condition, the pallor, the rapid loss of strength, and the fever, are the only things here which call our attention to acute tuberculosis, and render the diagnosis possible.

Finally, the discovery of tubercle bacilli in the blood is of the greatest diagnostic significance. Their detection is a difficult matter, but Weichselbaum and others have repeatedly succeeded in finding them.

**Prognosis.**—The cases described in literature as "cured miliary tuberculosis" are so uncertain in their diagnosis that they can not be regarded as convincing. We must therefore consider the prognosis as absolutely fatal. The differences in the course of the disease have been mentioned above.

**Treatment.**—Although drugs are absolutely powerless, still the case in hand must always receive treatment, since the diagnosis often can not be made out with absolute certainty. Our prescriptions are purely symptomatic. The cases with a typhoid course are to be treated just like typhoid, with baths, stimulants, etc. Tepid baths, and also local applications to the chest, expectorants, and narcotics, are indicated when the thoracic symptoms predominate. If meningeal symptoms set in, we may try ice, and also local blood-letting, with iodide of potassium internally.

## CHAPTER VIII.

## GANGRENE OF THE LUNGS.

**Etiology.**—The sole cause of pulmonary gangrene—that is, the death and putrid decomposition of the lung-tissue—is the entrance of the bacteria of putrefaction into the lungs. The opportunity for inhaling them is certainly very great, but the normal organism apparently possesses the property of nullifying them and making them powerless. Under certain conditions, however, they take root in the lung and cause the death of the pulmonary parenchymia, which then, as a result of the presence of these specific bacteria of putrefaction, succumbs to that peculiar form of putrid decomposition known as “moist gangrene.”

The factor which most frequently gives rise to the development of pulmonary gangrene is the entrance of organic foreign substances, especially bits of food, into the lungs. The bacteria of putrefaction either enter the lungs with the foreign substance, or they settle there later and set up a putrid decomposition, first in that portion of the lungs, and then in the neighboring lung-tissue. The entrance of organic foreign substances into the lungs occurs in different ways. It often happens from swallowing the wrong way, or from an accidental inhalation. In this way pulmonary gangrene may arise in previously healthy people, but it occurs especially in patients who are very low, very stupid, and soporose, and also in the insane, in patients who can not swallow or cough well, and in patients with paralysis of deglutition, as in bulbar paralysis. Bits of food may also reach the lungs from eructations and vomiting. Thus are explained the cases of pulmonary gangrene which occur in patients with cancer of the stomach, and, still more frequently, with cancer of the œsophagus. Putrid organic material may also reach the lungs from ulcerative and ichorous processes in the mouth, the pharynx, and the larynx. In cancer of the tongue, the pharynx, and the larynx, in other ulcerative processes, and in injuries or wounds from operations in the mouth and pharynx that have become septic, pulmonary gangrene may develop quite readily. Finally, septic foci in the vicinity may extend to the lungs or perforate into a bronchus. In this way a pulmonary gangrene may arise from the perforation through the pleura into the lungs of an ulcerated cancer of the stomach or a gastric ulcer, or in rare cases from vertebral caries, or from sanious lymph-glands.

In some cases the cause of the pulmonary gangrene can not be made out, since the entrance of a foreign substance has perhaps been wholly unnoticed, as may happen in children, or during sleep. We had a grown-up young woman under observation for a long time with pulmonary gangrene, and one day she coughed up several fragments of chicken-bones, but she could give no account of how they entered the lungs.

Experience teaches us that pulmonary gangrene is more apt to develop in persons with a general weak nutrition, in old, marantic people and drunkards, than in those who are healthy. The tendency of patients with diabetes mellitus to pulmonary gangrene is remarkable.

Pulmonary gangrene often develops secondarily to some other pulmonary affection. We have already spoken of the relations between it and foetid bronchitis. Foetid bronchitis, on the one hand, often leads to pulmonary gangrene through an extension of the process to the alveoli; and, on the other hand, where there is a gangrenous focus in the lungs, the bronchi are often infected to a wide extent by the putrid secretion coming from it, and then there arises foetid bronchitis. Both diseases often run into each other without any sharp boundary; but gangrene may develop secondarily in other affections of the lungs. A new infection with putrid material, however, is always requisite, and the affection of the

lungs that already exists furnishes merely a favorable soil. This is the only explanation of the process when croupous pneumonia "runs into gangrene," or when gangrene develops in catarrhal pneumonia, in bronchiectasis, or in phthisis.

Although the agents of putrefaction enter the lungs through the bronchi in most of the methods of origin of pulmonary gangrene that have been mentioned, they may also be transported into the lungs by the blood-current. We call these forms embolic gangrene. We find such gangrenous nodules in the lungs in connection with extensive gangrenous bed-sores, puerperal processes, suppurative caries of the bones, etc. In these cases the putrid material enters a vein from the seat of the primary process and is brought to the lungs, and here we find, as a result of the putrid character of the embolus, not a simple infarction, but an embolic gangrene.

**Pathological Anatomy.**—We more frequently find pulmonary gangrene in the lower lobes than in the upper, corresponding to its mode of origin. Either both lungs are affected or only one, and the right somewhat more frequently than the left. We distinguish a diffuse and a circumscribed form, according to the extent of the gangrene. Embolic gangrene belongs to the latter form, and its nodules, by preference, lie near the pleural surface.

We can easily recognize the anatomical changes in gangrene. The lung-tissue is changed to a discolored, dirty, greenish-gray mass, which gradually and progressively becomes dissolved, forming a most foul-smelling ichor. We find, left in it, necrotic fragments of tissue and vessels. Gangrene cavities, with irregular, ragged walls, are formed from the partial expectoration of the softened gangrenous nodule. The lung-tissue in the vicinity of the peculiar nodule is to a greater or less extent inflamed, partly in the form of catarrhal pneumonia, partly in the form of circumscribed croupous pneumonia. The inflamed parts in the vicinity are gradually involved in the gangrene, so long as the process extends, but finally a suppurating line of demarkation may be formed about the gangrene, the whole gangrenous fragment is in a measure sequestered, encapsuled, and gradually expelled, and so healing becomes possible. We have already stated that foetid bronchitis may arise from a gangrenous nodule.

Whenever a gangrenous nodule reaches the pleura, a purulent and usually a sanious pleurisy follows from direct infection. Pneumothorax may arise from perforation of a gangrenous cavity.

**Clinical History.**—The symptoms of gangrene depend for the most part upon the local affection in the lung. The condition of the expectoration is characteristic, and it alone may decide the diagnosis.

In many of its conditions the expectoration greatly resembles that of foetid bronchitis, and indeed a great part of it does not come directly from the gangrenous nodule, but is the secretion of the diseased bronchi. The penetrating stench of the sputum, a most repulsive, putrid odor, is very striking. The patient's breath and cough also have this bad smell, which infects the whole vicinity. The amount of the sputum is usually large; it may reach ten or twenty ounces (200–500 c. c.) in twenty-four hours. If the sputum is collected in a glass it forms three layers, as in the sputum of foetid bronchitis—an upper layer, muco-purulent, greasy, consisting in part of nummular sputa, and covered with much froth; a middle serous layer, in which some firm masses from the upper layer float; and a lower layer, almost wholly of pus, but greasy and greenish-yellow, which usually contains many large and small plugs and shreds of tissue. We find in these plugs, on microscopic examination, beautifully twisted needles of the fat acids (see Fig. 21, p. 156) imbedded in countless bacteria, fat-drops, and detritus, and often collected in large bundles; but besides these we find in it the constituents of the parenchyma of the lungs, and this alone is the decisive factor in distinguishing between

pulmonary gangrene and simple foetid bronchitis. Traube's theory—that elastic fibers are not found in the expectoration in pulmonary gangrene, or that they are rare, because the elastic tissue also is destroyed by the gangrene—is untrue. We have almost always found elastic tissue in abundance in the expectoration, and also other fragments of parenchyma, lung-pigment, etc. Which of the coarse, rod-like bacteria, described by Leyden and Jaffé as *leptothrix pulmonalis*, are the special bacteria of gangrene is not decided. The chemical examination of the sputum shows the presence of those substances which may always be found in the putrefaction of organic matter—tyrosine, leucine, ammonia, sulphuretted hydrogen, butyric acid, valerianic acid, caprylic acid, etc. The fresh sputum usually has an alkaline reaction, but on standing it becomes acid.

Many cases of gangrene lead to erosion of the vessels and severe hæmoptysis. Slight admixtures of blood in the sputum are not infrequent.

The other symptoms on the part of the lungs are not especially characteristic of gangrene. Most patients complain of cough, pain in the side, and more or less severe dyspnoea. Physical examination, as a rule, permits us to make out the seat of the nodule, but not always, since the physical signs, of course, depend upon the situation and extent of the gangrene. Small nodules, situated centrally, often give no objective evidence of their presence. Every extensive infiltration, however, must cause dullness on percussion. Over the area of dullness we hear bronchial respiration, and usually quite numerous moist râles. If a gangrenous cavity is formed, the physical examination may show plain symptoms of a cavity—tympanitic resonance on percussion, amphoric respiration, large moist râles, etc.

The physical signs are sometimes due to the accompanying pleurisy; the dullness is more intense, the respiratory murmur and the vocal fremitus are diminished, and the adjacent organs are displaced by the abundant effusion; but an absolute diagnosis of an accompanying pleurisy is often to be made only by an exploratory puncture. We have already spoken of the occasional development of pneumothorax.

In many cases there is fever, of quite an irregular character and of very varying intensity. In the cases where the gangrenous nodule is sequestered, and where the secretion can be freely emptied through the bronchi, and where, accordingly, there is no absorption of septic material into the blood, the fever also may be entirely absent.

We often see gastric and intestinal symptoms in pulmonary gangrene, the disturbance being without doubt due to swallowing some of the foetid sputum. Many patients complain of loss of appetite, and sometimes of vomiting or diarrhoea. We also see rheumatic pains in the joints and muscles, as in foetid bronchitis. It is also worthy of note that secondary abscess of the brain has been repeatedly observed in pulmonary gangrene (see page 741). We must bear this in mind if very severe cerebral symptoms, like somnolence or paralysis, develop in the course of a gangrene.

The general course of the disease shows very great variations. In all cases where the pulmonary gangrene is secondary to some other affection, the course and the general type of the disease depend very largely upon the primary attack, but the cases of idiopathic gangrene also present great variations. The onset is either quite gradual and slow, or quite acute, and associated with fever and thoracic symptoms. The stinking expectoration and the bad odor from the patient's mouth first direct the attention to the existence of putrid processes in the lungs. The disease is usually very chronic, lasting for months or even years. Many remissions and intermissions occur. With proper care and treatment we may see a clear improvement, and often apparently a complete cessation of the disease. The bad odor ceases, the expectoration diminishes or disappears entirely, and the

patient's strength and nutrition become almost normal; but relapses may occur after long intervals. Where the affection is of slight extent we may even see a complete recovery.

Pulmonary gangrene always takes a worse course in previously weak and marantic persons, and an unfavorable termination may follow in a comparatively short time. Death ensues either from a general loss of strength, as a result of the disease, or from complications, such as pulmonary hæmorrhage, ichorous pleurisy, pneumothorax, or abscess of the brain. Rupture of an ichorous empyema outwardly, or into the peritoneum, or into other cavities, is rare.

Special mention must be made of the fact that the symptoms of pulmonary gangrene are not always so very pronounced. In people who are weak and run down we often see pulmonary gangrene at the autopsy, although during life there have been no marked symptoms, not even offensive sputum nor the fætor from the mouth.

**Diagnosis.**—The diagnosis can be made with certainty only when the characteristic sputum is present. We can decide whether the sputum comes from a fœtid bronchitis or from the fœtid contents of a bronchiectasis, or from actual gangrene, only by finding under the microscope the remains of lung-tissue in the expectoration. Physical examination in gangrene, at least in part of the cases, also gives the signs of infiltration or of cavity-formation in the lungs.

**Prognosis.**—The prognosis depends first upon the nature of the underlying disease, and then upon the extent of the affection, the strength of the patient, and the possibility of sufficient care and proper treatment. If the process in the lung becomes sequestered, marked improvement may follow, even in the severest conditions; but we must always remember that a relapse is possible. We have already mentioned the dangers which may cause a fatal termination in pulmonary gangrene.

**Treatment.**—Prophylaxis plays an important part in those cases where there is danger of the entrance of bits of food into the air-passages from defective deglutition. We must think of the possibility of this with all patients who show great stupor, and also with patients who have paralysis of deglutition, in order to watch them while taking food, and eventually to try artificial feeding with the œsophageal tube.

The treatment of already existing pulmonary gangrene has, as its chief aim, to check the putrid processes of decomposition in the lungs. Unfortunately, the remedies at our command are not in all cases sufficient for this. The different disinfecting inhalations are the most effective. They are used in the same way as in fœtid bronchitis (*vide supra*). Turpentine deserves the most confidence, and it may also be given internally with good results. According to Lépine, however, terpine acts still better than does turpentine. We may also call attention to inhalations with carbolic acid, Curschmann's carbolic mask, inhalations with salicylic and boracic acids (4 parts of salicylic and 20 of boracic acid to 1,200 of distilled water), bromine (bromine and bromide of potassium, 2 parts of each to 1,000 of water), and similar substances.

Besides oil of turpentine, other internal remedies are recommended: half a grain to a grain (grm. 0.03–0.06) of acetate of lead every two hours, creasote, carbolic acid, etc. Their action is uncertain. Of late, myrtol has been greatly extolled. It is given in capsules containing grains iʒss. (0.15), of which two or three are to be taken every two hours.

The general treatment of the patient is very important—he should have good food, and live in as good air as possible. We must treat the pain in the chest and the cough symptomatically, local applications and morphine being most useful. The fever seldom gives occasion for direct interference. In general, cold spong-

ing, or else tepid baths, suffice, so that quinine is only rarely to be used. We may try to relieve the gastric and intestinal symptoms by giving antiseptics internally, especially by small doses of muriatic acid, salicylic acid, or creasote, as well as by the ordinary remedies, such as bitters and opium.

If a secondary ichorous pleurisy develops, with or without pneumothorax, removal of the fluid by operation is necessary, if the patient has sufficient strength to bear it.

## CHAPTER IX.

### DISEASES FROM THE INHALATION OF DUST.

(*Pneumoconiosis.*)

ALTHOUGH there are a number of important contrivances in the respiratory apparatus to impede the entrance of foreign substances contained in the air into the lungs, still, if a person remains in a dusty atmosphere, so many particles of dust may be inhaled that they are not without effect on the lung-tissue. The diseases from the inhalation of dust are usually purely professional diseases, which occur especially in workmen whose occupation brings with it the continual inhalation of some kind of dust. Since we do not have to deal with a specific influence, as in the inhalation of infectious substances, but usually only with a mechanical effect all diseased conditions excited by the different sorts of dust may be treated in common.

We must first mention, however, a condition of the lungs which can scarcely be regarded as pathological, although it has its origin in the constant inhalation of dust, especially of coal-dust—the ordinary black pigmentation of the lungs. There can now no longer be any doubt, although there was once a long dispute about it, that the black pigment in the lung comes, in large part at least, from the inhalation of carbon. The particles of carbon pass into the lungs themselves, and thence into the bronchial glands by means of the lymphatics. Only a part of the coal-dust inhaled is removed with the expectoration, and it may easily be found in it microscopically, and often by the naked eye, as we see it in the well-known black expectoration which we often have in the morning, if we have spent the previous evening in a room filled with smoke. In Germany, Traube was the first to discover the particles of carbon in the expectoration of a charcoal-burner. In the man's lungs, after death, the vegetable formation of these particles could be recognized, and Traube gave the correct explanation of them. In workmen who inhale large amounts of charcoal-dust, anthracite coal-dust, soot, or graphite, the "normal" pigmentation of the lung passes into a pathological condition, *anthracosis pulmonum*.

Zenker first discussed comprehensively the fact of the entrance of the different sorts of dust into the lungs and the consequent results. Besides the anthracosis already mentioned, the pulmonary disease from inhaling the dust of flint and other stones is of especial importance, the so-called stone-cutter's lung—*chalicosis pulmonum*—and also that from inhaling metallic dust, especially oxide of iron—*siderosis pulmonum*. The "stone-lungs" have been observed in workmen in the stamping-rooms of glass-factories, in mill-stone cutters, stone-polishers, stone-hammerers, plasterers, workers in porcelain, masons, slate-quarrymen, potters, etc. "Metal-dust lungs" occur in file-cutters, iron-workers, mirror-polishers, and especially in grinders, who inhale a mixture of stone- and iron-dust. The first case of a "red iron lung" was observed by Zenker, in a girl who had inhaled a thick dust of iron for ten or twelve hours a day. Her work was to color blotting-paper

with a powder of red oxide of iron. Among the other forms of dust which may give rise to pulmonary disease we may mention tobacco-dust, cotton-dust, saw-dust, and flour-dust.

The anatomical changes in the "dust-lungs" consist of a chronic bronchitis, and especially a chronic interstitial inflammation, leading to the formation of connective tissue, and caused by the mechanical irritation of the foreign body. The lungs are studded with nodules, which feel hard to the touch, and which grate on section with a knife. All of these nodules consist of firm connective tissue, in which the particles of stone or iron are encapsuled. By the union of single nodules we may get more extensive induration and cicatricial formation. Chemical examination of such lungs gives, as might be supposed, a large amount of silicic acid, iron, etc.

In most of the cases which come to autopsy we find further changes in the lungs, which are not the immediate result of the inhalation of dust, but consist of sequelæ and complications. Chronic diffuse bronchitis in the worker in dust, like any other chronic bronchitis, may give rise to pulmonary emphysema, and later to cardiac hypertrophy, etc. We very often find in the lungs co-existing and pronounced tubercular changes. It need not be stated more fully that these changes are not the direct result of the inhalation of dust, but that the changes in the lungs set up by such an inhalation furnish merely a favorable soil for infection with tuberculosis. In most cases, the "dust-lungs" acquire a marked clinical significance chiefly from the sequelæ mentioned—namely, emphysema and tuberculosis. The circumscribed nodules of interstitial pneumonia have no very marked symptoms following them. In all cases where there is a fatal termination, with pulmonary symptoms, we should regard the immediate action of the dust as much less the cause of death than are the secondary diseases.

The actual points to be considered in judging of the clinical symptoms of the diseases from inhaling dust are contained in what has been said. The symptoms are those of common chronic bronchitis, or pulmonary emphysema, or phthisis, and attention to the injurious influences associated with the patient's calling is the only possible way of making a diagnosis, but in individual cases it may always be a matter of doubt how far other accidental causes of disease may come into play.

The prognosis depends, in the first place, upon whether the patient can be removed from the action of these injurious influences or not, but we must also mention the fact, which has been often observed, that many people get somewhat used to the dust. After they have once recovered from the initial bronchitis, such people can live in an atmosphere of dust for a long time without any noticeable injury.

The prophylaxis of diseases from inhaling dust forms an extended chapter in the hygiene of occupations, which we can not dwell upon here. The workman must be taught the danger to which he is exposed, and the danger itself must be diminished as much as possible by sufficient ventilation of the work-rooms, by cleanliness, and, under some circumstances, by a change in the technicalities of the business.

We need not give any special data regarding the treatment of diseases from inhaling dust. They are founded on the same principles as are given for the treatment of chronic bronchitis, emphysema, and chronic pulmonary tuberculosis.

## CHAPTER X.

## EMBOLIC PROCESSES IN THE LUNGS.

*(Hæmorrhagic Infarction of the Lungs.)*

**Ætiology.**—The sources from which the material for an embolic plugging of branches of the pulmonary artery comes lie either in the right side of the heart or in the veins of the body. Pathological anatomy teaches us how often thrombi are formed in the veins, especially in the veins of the lower extremities and in the pelvic veins, and in the right side of the heart, in the recesses between the trabeculæ, in the auricles, on the valves and the chordæ tendineæ, and at the apex of the ventricle. The particles, torn loose from thrombi so situated, are carried on by the blood-current, reach the lungs, plug a larger or a smaller branch of the pulmonary artery, according to the size of the particles, and thus cause further changes in the lung-tissue. Since the branches of the pulmonary artery are "terminal arteries," and since thus the vascular territory belonging to each branch can not be supplied, or can be supplied only to a small amount, with blood by collateral circulation from other vessels, the closure of a branch of the artery shuts the territory supplied by it out of the circulation. The pressure, in the part of the vessel lying peripherally to the point of plugging, becomes almost nil, and, as a result, there is a backward current into the region shut off, flowing from the capillaries in the vicinity, and even from the veins belonging to it. Thus we get a typical "engorgement." The walls of the capillaries and veins, in which the normal blood-current has ceased, lose their natural consistency as a result of this. The vascular walls become abnormally pervious. The fluid of the blood, the white blood-corpuscles, and also very many red blood-corpuscles, penetrate through the walls of the vessels into the surrounding tissue, and change it into the so-called hæmorrhagic infarction.

Every embolic closure of a branch of the pulmonary artery does not necessarily result in the formation of an infarction. Upon the sudden plugging of a main trunk, or of several large branches of the pulmonary artery, death may ensue at once, so that naturally all further changes in the lung-tissue cease. We also find quite frequently, especially in central portions of the lung, embolism of single branches of the pulmonary artery, without the formation of an infarction. In such cases there must necessarily be a little circulation in the vascular territory which has been shut off, either by anastomoses between the territory of the pulmonary artery and that of the bronchial or mediastinal artery, or by the neighboring capillaries, whose arteries of supply remain open.

The changes thus far described are the result of a purely mechanical closure of a pulmonary artery. We have noticed this especially where simple fibrinous plugs have given the occasion for the embolic process. Pulmonary infarctions are most frequent in chronic heart disease, in all forms of primary and secondary dilatation of the heart, but especially in disease at the mitral orifice, and in mitral stenosis. Thrombus formation is frequent in the dilated right side of the heart, and furnishes material for pulmonary emboli; but these emboli are seen in all other possible conditions of disease, in which thrombosis in the right side of the heart or in the veins may occur.

The changes in the lungs assume quite a different appearance if the embolic material is not simple fibrine, but if it contains at the same time some specific infectious matter. If emboli reach the lungs from an acute malignant endocarditis in the right side of the heart, or, as is most frequently the case, from a purulent (septic) phlebitis anywhere in the body, giving rise to a puriform, liquefying thrombus, the specific factors in inflammation—that is, bacteria—get into the

lungs. Thus arise embolic abscesses and embolic gangrenous nodules in the lungs. We have already spoken of the latter, and the former are among the most constant lesions in every typical pyæmia.

The fundamental facts as to the occurrence and significance of embolic processes in general, and those located in the lungs in particular, were discovered by Virchow. For the fuller understanding of the results of embolic closure of the vessels we must thank chiefly the labors of Cohnheim.

**Pathological Anatomy.**—Hæmorrhagic infarctions may involve one or more lobules, or almost a whole lobe of the lung, according to the situation of the embolus. Most infarctions are situated at the periphery of the lung, and have approximately a conical shape, corresponding to the extent of the region of the vessel. The base of the cone lies against the surface of the pleura. It generally projects a little above that surface, and its dark color can usually be plainly recognized through it. The pleura itself is the seat of a fibrinous inflammation at the point to which the infarction reaches, and sometimes for a large space around it. The conical shape of the infarction is plainly recognized on section. The lung-tissue is changed to a firm, fragile, uniformly black-red tissue, devoid of air. The embolus can usually be readily found in the branch of the pulmonary artery leading to the infarction. Under the microscope we see a diffuse infiltration of tissue, with red blood-corpuscles in the infarcted portion. The alveoli and finer bronchi are also filled with coagulated blood. Under favorable circumstances, in cases of longer standing, the blood may be reabsorbed in part. The lung again contains air, but it remains much pigmented in that place, and more or less indurated from the development of interstitial connective tissue.

Hæmorrhagic infarctions are usually situated in the lower lobes, and more frequently on the right side than on the left.

The smaller embolic abscesses are sometimes very numerous, and are disseminated over the whole lung. In larger abscesses the conical shape may often be plainly recognized. Where an abscess extends to the pleura, a purulent pleurisy arises from direct infection. Combinations and transitional forms between the ordinary hæmorrhagic infarction and embolic abscesses are occasionally found in the lungs.

**Symptoms.**—We often find at the autopsy embolism of single branches of the pulmonary artery, with or without infarction, which has caused no symptoms at all during life.

Embolism of the main trunk, or of a large branch of the pulmonary artery, may cause sudden death, as has been repeatedly observed in patients with heart disease, or with venous thrombosis. If death be not immediate, sudden severe dyspnoea and oppression arise. The diagnosis may at least be suspected in such a case if we know of a possible source for an embolus. In some instances, where an embolus is situated in a large branch of the pulmonary artery, but has not completely filled it, we can hear a systolic vascular murmur over the affected spot, as has been observed by Litten. The diagnosis, however, becomes certain if the further signs of infarction appear later.

The most characteristic symptom of infarction in the lungs is the bloody expectoration. If we see quite suddenly bloody sputum in a patient with mitral stenosis, we are usually right in assuming a hæmorrhagic infarction of the lung. Either the sputum consists almost entirely of dark blood, or the blood is mixed with more or less mucus; but there is never much air in it. The bloody expectoration often lasts for several days.

We try to learn more of the size and situation of the lesion by a physical examination of the lungs. Of course this often gives a negative, or at least a doubtful, result. It goes without saying that small infarctions, and also those which

are central, can not be made out by physical examination. Large peripheral infarctions may give rise in many cases to dullness on percussion, crepitant râles, and harsh or bronchial respiration, but it is often hard to decide in an individual case whether the physical signs which we meet with are not due to other pathological changes in the lungs, like bronchitis or hydrothorax. We sometimes hear a pleuritic friction-sound in some part of the chest a few days after we suspect that an infarction has occurred, by which the diagnosis gains additional certainty. We have already mentioned the subjective symptoms in embolism of a large pulmonary vessel—sudden dyspnoea and oppression. Small nodules often cause no special symptoms, but in other cases the patient feels a severe pleuritic pain, due to irritation of the pleura.

Fever may be wholly absent, though we sometimes see a moderate rise of temperature at the onset.

The embolic abscesses in the lungs hardly ever give rise directly to clinical symptoms. They form a part of the general picture of pyæmia and similar general infectious processes. Marked symptoms on the part of the respiratory apparatus are seen only when the abscesses are present in very large number. If an empyema develops from a focus which extends to the pleura, it sometimes gives rise to definite physical signs.

It follows from all that has been said before, that in the diagnosis of embolic processes the chief stress must always be laid on the presence of an ætiological factor. We must regard the bloody sputum as the main direct symptom in hæmorrhagic infarction. Embolic abscesses in the lungs may often be suspected in pyæmic diseases, but they can hardly ever be made out absolutely.

The prognosis is entirely dependent upon the underlying disease. In heart disease the occurrence of a hæmorrhagic infarction is usually on the whole an unfavorable sign, since it points to weakness of the right ventricle, and hence to the formation of a thrombus in it; yet it often happens that the symptoms of a pulmonary infarction may pass away entirely.

We need not give special directions for treatment. It is in part purely symptomatic, and in part coincides with the treatment of the underlying affection. As regards prophylaxis, we must bear in mind the absolute necessity of as perfect rest as possible in those patients in whom the presence of venous thrombi, as in the femoral veins, suggests the possibility of pulmonary embolism.

---

## CHAPTER XI.

### BROWN INDURATION OF THE LUNGS.

(*Lungs of Heart Disease.*)

In heart disease, especially in mitral stenosis, we often find a peculiar change in the lungs, whose origin must be sought in the long-persisting engorgement of the pulmonary circulation. The lungs are hard and dense, and show on a fresh section an abnormal brownish-yellow color. In the larger pulmonary vessels, the arteries and veins, there is a thickening and cloudiness of the intima as a result of the stasis. We see here and there on the surface of the section, and beneath the pleura, little dark spots of pigment and fresh hæmorrhages. We term this condition brown induration of the lungs.

Microscopic examination shows that the capillaries are evidently dilated and twisted as a result of the persistent stasis. They even extend a good way into the

alveoli, whose lumen is thus actually diminished.\* The interstitial connective tissue seems somewhat thickened, and we find in it many pigment granules, the remains of the extravasated and decomposed red blood-corpuscles. According to Rindfleisch, the muscular constituents of the parenchyma of the lung, the smooth muscular fibers at the entrance and in the walls of the alveoli, show a distinct hypertrophy. In the intima of the larger vessels we often find fatty degeneration of the endothelium, and sometimes even fatty degeneration of the muscular coat.

As regards the clinical significance of brown induration of the lungs, it is possible that the extensive diminution of the lumina of the alveoli throughout the whole lung may contribute somewhat to the increase of the dyspnoea in heart disease, but in practice this factor can not be separated from the other causes which produce dyspnoea.

We have no certain factors by which to diagnosticate brown induration of the lungs during life. The anatomical lesions, too, show a certain variation, not always to be explained, in that, under apparently the same conditions, the brown induration is often very marked, and often only extremely slight. In cases where we find this induration in the cadaver we sometimes hear, during the patient's life, a very sharp, puerile respiratory murmur, which seems to be characteristic of many cases of the "heart-disease lung." We might lay still more stress upon the presence of large, characteristic cells in the expectoration, which are thickly filled with large and small yellow or brown pigment-granules. These large pigmented cells are in all probability white blood-corpuscles, which have taken up the pigment from the red blood-corpuscles destroyed within the alveoli. At the autopsy we also find these cells lying within the alveoli. Besides these pigment-cells we also frequently see the still intact red blood-corpuscles in the expectoration of patients with heart disease.

The prognosis and treatment coincide with those of the underlying cardiac disease.

## CHAPTER XII.

### TUMORS OF THE LUNGS. CANCER OF THE LUNGS. ECHINOCOCCUS OF THE LUNGS. PULMONARY SYPHILIS.

1. NEW GROWTHS IN THE LUNGS. CANCER OF THE LUNGS.—Most of the new growths which are met with in the lungs are of a secondary nature. Secondary cancers are sometimes found in the lungs, with carcinoma of other organs, whose origin may always be explained by supposing a growth of the primary tumor into a vein, and the consequent carriage of the germs of the growth to the lungs. These secondary nodules in the lungs usually cause no special clinical symptoms, unless they are very numerous and extensive, when they give rise to dyspnoea, and physical signs. Several years ago there came to the clinic in Leipsic a case of secondary, and very extensive, miliary carcinosis of the lungs, which ran a brief and fatal course, simulating acute miliary tuberculosis with predominant pulmonary symptoms.

We must mention enchondroma among the other secondary new growths, but it may also occur primarily in the lungs in very rare cases. Secondary sarcoma of the lungs is also very rare. We have seen a very extensive form of it after

\* This view had been universally accepted, but it has been somewhat shaken by Basch. He believes that the effect of passive congestion upon the pulmonary capillaries is to stretch them, thus tending to make the lumen of the alveoli not smaller, but larger (*vide* chapter on heart disease).

primary sarcoma of the bronchial glands, and also in a case of lympho-sarcoma of the cervical lymph-glands, where the sarcoma had grown into the jugular vein; and, finally, we have seen it repeatedly in congenital primary sarcoma of the kidneys (*vide* chapter on new growths in the kidneys).

Among the primary new growths in the lung, cancer is the only one which has much clinical significance. In its clinical relations we can also rank with it certain malignant, metastatic forms of alveolar sarcoma. The typical cancer of the lungs is always a cylindrical-celled carcinoma, which undoubtedly arises from the bronchial epithelium. It is especially common in elderly people, over forty, and seems to be found somewhat more frequently in the right lung than in the left, and in the upper lobes than in the lower. By its diffusion the lung-tissue in the parts affected by cancer is changed to a yellowish-gray and quite soft and crumbling mass, devoid of air. We can usually scrape away from the section the characteristic cancer-juice, in which the microscope shows the typical cancerous elements. The pleura is very often involved. The new growth has either extended directly into it, or single, and more circumscribed, secondary nodules have formed in it. The lymph-glands are almost invariably affected, especially the bronchial glands, and also the axillary and cervical glands. Secondary carcinoma of other organs is rare, but it is found in some cases in the other lung, the liver, the brain, and elsewhere.

It is almost always difficult to interpret correctly the clinical symptoms of cancer of the lungs at the beginning of the disease. They are referred to some other, more frequent chronic pulmonary disease, such as chronic bronchitis, phthisis, or pleurisy, but in the further course of the disease we succeed, at least in a number of cases, in making a correct diagnosis. In other cases, especially in old people, the disease may remain latent.

The general symptoms in the lungs have little that is characteristic. The patient complains of gradually increasing difficulty in respiration, and of pressure and distress in the chest, which may finally increase to the most intense dyspnoea. Most patients suffer very much from the labored, frequent, and spasmodic cough. The expectoration in some cases has no peculiarity, but it often assumes, at least for a time, a characteristic consistency which is extremely important for diagnosis. It contains blood, and also has a peculiar "currant-jelly-like" appearance. Under the microscope we can sometimes make out the characteristic elements of the tumor in it. Severe hæmoptyses are also seen in cancer of the lungs.

Physical examination of the lungs gives a positive result in many cases, such as dullness, bronchial respiration, diminished respiration, râles, and sometimes pleuritic friction-sounds, none of which has anything characteristic in itself, but they are of distinct significance in making out the seat and the extent of the new growth. Special mention must be made of the often-noticed diffuse projection and swelling of the diseased side.

The occurrence of certain sequelæ is of great diagnostic significance. The chief one is the discovery of swelling in the lymph-glands in the neck or axilla, and also a number of symptoms of compression, which either are produced directly by the new growth, or are due to the secondary enlargement of the lymph-glands. Pressure on the superior vena cava, or a large branch of it, causes œdema in the face, neck, over the wall of the chest, or in one arm. The subcutaneous veins in the regions named appear dilated and tortuous. Pressure on the œsophagus causes difficulty in deglutition; pressure on the brachial plexus, intense neuralgic pains and paresis of one arm; pressure on the recurrent nerve, paralysis of the vocal cords and hoarseness; pressure on the trachea or a primary bronchus, the symptoms of tracheal or bronchial stenosis.

Besides the symptoms already mentioned we must consider the general symp-

toms. As in carcinoma in general, so in pulmonary carcinoma, the well-known cancerous cachexia gradually develops. The patient grows dull, loses his appetite more and more, disturbances of digestion and sometimes moderate elevations of temperature develop, until he finally succumbs to general marasmus.

The whole duration of the disease is from six months to two years. The prognosis is fatal. The treatment can be only purely symptomatic, and we employ the same remedies as in other pulmonary affections.

We must still briefly consider a new growth in the lungs which is extremely interesting from a theoretical point of view. In workmen in the cobalt mines of Schneeberg, in the Saxon Voigtland, the development of malignant lymphosarcomata in the lungs, with the occasional formation of metastases in the glands, the liver, the spleen, etc., is of frequent occurrence. The disease runs its course under the type of a chronic pulmonary affection, and almost always ends fatally. The endemic occurrence seems to point to an infectious origin for the tumor.

2. ECHINOCOCCUS OF THE LUNGS.—Primary echinococcus in the lungs is very rare. In most cases the echinococci are brought to the lungs secondarily from other organs, either by way of the blood-current, or, as is far oftener the case, by perforation of an echinococcus of the liver through the diaphragm.

The symptoms of echinococcus of the lungs are manifold. The parasite sometimes remains entirely concealed. In other cases a more or less severe, and often febrile, affection of the lungs, is developed, with pain in the chest, cough, and sometimes bloody expectoration, and dyspnoea. Physical examination of the lungs gives in some cases dullness, absence of respiratory murmur, and diminished vocal fremitus, while after the expectoration of the echinococcus (*vide infra*) symptoms of a cavity may ensue. A correct interpretation of all these symptoms is possible only when, as has often been observed, the echinococcus cysts are coughed up, or at least when parts of them, like the membranes or the hooklets, are found in the expectoration.

The termination of the disease may be favorable if the echinococci are expectorated, or if we succeed in removing them by operative means. We can hardly hope to be able to kill the parasite by inhalations of turpentine or benzine. Sometimes the echinococcus cyst becomes gangrenous, or suppurates. Rupture into the pleura, into the peritoneum, into the pericardium, and externally, has also been observed. This last termination is the most favorable, since otherwise, if the affection progresses, a fatal result may be caused by the sequelæ, or rarely by the occurrence of suffocation. The details of the natural history of the echinococcus are given in the chapter on echinococcus of the liver.

3. PULMONARY SYPHILIS.—This would also be the place to speak of syphilitic new growths in the lungs, but, in our opinion, in spite of the quite abundant literature of this subject in recent times, no definite statement as to pulmonary syphilis can be made. Those physicians who are disposed to consider every pulmonary disease in a previously syphilitic subject to be of a syphilitic nature, certainly regard many things as pulmonary syphilis which have nothing at all to do with syphilis. At least, we have found that all those cases which at first suggested a diagnosis of pulmonary syphilis, finally, upon more accurate examination and after longer observation, have turned out to be something else, usually tuberculosis. The only form of pulmonary syphilis that has been established pathologically is syphilis of the larger and medium-sized bronchi, which is recognized at the autopsy by extensive radiated cicatrices in the bronchial mucous membrane, and which sometimes lead to stenosis. Single gummatous nodules in the lungs are of the greatest rarity. We sometimes find in the pleura peculiar radiated cicatrices, which perhaps are of syphilitic origin. Practically we are always justified, if severe and otherwise inexplicable pulmonary symptoms occur in a previ-

ously syphilitic subject, in trying specific treatment; but very seldom do we get any good result from it. The pulmonary syphilis of the new-born, which occurs in the form of single nodules or as a diffuse syphilitic infiltration, the so-called *pneumonia alba*, has only a pathological interest.

## SECTION V.

### DISEASES OF THE PLEURA.

#### CHAPTER I.

#### PLEURISY.

(*Pleuritis*.)

**Ætiology.**—We make the general distinction of a primary and a secondary pleurisy.

By primary pleurisy we mean those cases where previously healthy people are attacked with an inflammation of the pleura. We have no doubt that such cases occur, but they are much rarer than is generally believed, for many cases of secondary pleurisy give one the impression of a primary disease, either because the primary affection has caused no symptoms up to that time, or because it can not be detected. Taking cold is one of the chief exciting causes of primary pleurisy, and mechanical injury may also sometimes act as a cause.

Secondary pleurisy arises, in a great majority of cases, from a direct invasion of the pleura by an inflammatory process originating in some neighboring organ. We have already had to point out repeatedly, in the description of pulmonary diseases, how the different pathological changes in the lung likewise involve the pleura if they reach that organ. Thus arises the pleurisy in croupous pneumonia, in lobular catarrhal pneumonia, in pulmonary gangrene, in hæmorrhagic infarction, and in embolic abscess. Since many of these affections often develop in the course of the most diverse diseases, we can easily understand that pleurisy is a not infrequent complication of all possible severe diseases.

By far the most important secondary form is tubercular pleurisy. The teaching of daily clinical and pathological experience is that the ordinary chronic pulmonary tuberculosis is almost constantly complicated with pleurisy. The latter is often entirely subordinate to the phthisis, but in many cases certain subjective symptoms, like pain, and also physical signs, are certainly to be referred to the pleurisy. Of much greater practical importance, however, are those cases of tubercular pleurisy which arise as an apparently primary pleurisy. Among these are the larger part of all ordinary "pleuritic effusions." The type of the disease is wholly dominated by the pleurisy. This may improve decidedly, as often happens, or even in many cases be completely cured (*vide infra*), but, if we keep the patient long enough under observation, marked signs of tuberculosis usually arise later on (see the general course of the disease), whence it follows that the initial pleurisy must be regarded, in an ætiological sense, as tubercular. The special origin of tuberculosis in these cases is not always quite clear. There is certainly a small tubercular focus often present in the lungs, which has caused no symptoms in itself, but which became the point of origin for a pleurisy. Not infrequently the pleurisy seems to start from a tuberculous bronchial gland breaking into the pleural cavity and infecting the latter with tuberculous virus.

Other organs besides the lungs may be the point of origin for a pleurisy. Thus pleurisy arises from affections of the ribs or vertebrae, such as caries, from perforation of an œsophageal cancer, etc. Inflammations of other serous membranes are especially apt to invade the pleura. Thus it arises as a result of a pericarditis or peritonitis. Since the pleural and peritoneal cavities are in direct communication with each other by the lymphatics of the diaphragm, we can conceive that both a purulent and a tubercular peritonitis may result in a secondary pleurisy.

Secondary pleurisy sometimes arises in the course of certain diseases in another way. In acute rheumatism, in rare cases, a pleurisy develops, which must be considered due to the specific causes of the disease. In chronic nephritis and in genuine gout we sometimes see pleurisy of which the precise origin is as yet not certainly known. Perhaps in these conditions the abnormal accumulation of the products of tissue-metamorphosis in the blood and the tissues is the cause of the development of inflammation.

**Pathological Anatomy.**—The inflamed pleura is markedly injected, it has lost its normal luster, and instead has a dull surface. This dullness is due to the coagulated fibrinous exudation upon the pleura, the exudation, in mild cases, forming only a thin layer. In more advanced cases, however, the surface of the pleura is covered with thick, rough, and shaggy masses of fibrine. As long as the fluid in the pleura is little or not at all increased, we speak of a simple fibrinous or dry pleurisy (*pleuritis fibrinosa vel sicca*).

In other cases, however, besides the layer of fibrine there is an abundant exudation of fluid from the capillaries of the pleura, forming a pleuritic effusion. This is ordinarily of a simple serous character—serous and sero-fibrinous effusions. The fluid collects between the surfaces of the pleura, or, if there is at the same time an abundant coating of fibrine, between the gaps and in the meshes of the fibrinous exudation. In such cases there are often many flakes of fibrine floating in the fluid.

In every serous effusion we also find a number of pus-corpuscles, which give to it a slight cloudiness, but if the number of pus-corpuscles increases very much, we have a fibrino-purulent or a purely purulent exudation. This is always due to the presence of a specific organized poison which excites the suppuration. The pleurisy which comes from embolic abscesses, from gangrenous foci in the lungs, and from carious ribs, and those which arise from the rupture of tubercular cavities into the pleura, are almost always of a suppurative character. We call the purulent pleuritic effusion empyema. If putrefactive agencies enter the pleural cavity at the same time with the pus poison, as in the pleurisy which develop in pulmonary gangrene, the purulent exudation assumes an ichorous, putrid character—ichorous effusion.

Under certain circumstances the effusion assumes a hæmorrhagic character—hæmorrhagic effusion—especially if hæmorrhages arise from the old or newly formed capillaries dilated by the inflammation. They arise partly by diapedesis and partly from rupture of the walls of the vessels. The exact cause of the hæmorrhages is usually unknown. We know by experience that hæmorrhagic effusions are most frequent in tubercular pleurisy, a fact which is of diagnostic importance. Hæmorrhagic pleurisy is also a frequent complication of septic—especially puerperal—diseases, as a result of embolic affections of the lungs. We can often refer the onset of a hæmorrhagic pleurisy, too, to a general hæmorrhagic diathesis, as in scurvy.

The amount of fluid collected in one pleural cavity is, in the majority of cases, somewhere between a pint and a quart (500-1,000 c. c.), but it may reach three or four quarts. Every large effusion must influence the position of the yielding walls

of the pleural cavity, the chest-wall, the lungs, the mediastinum, and the diaphragm, through the consequent increase of pressure in the affected pleural cavity; and the resultant symptoms of pressure in the neighboring organs are of the greatest clinical significance. Attention is first called to the lungs themselves. Since the normal lung is expanded in the thorax beyond its elastic equilibrium, it will retract as soon as a part of the pleural cavity is occupied with fluid. Until it has reached its position of elastic equilibrium there can be no question of a positive pressure on the lung. The lung floats on the effusion, in a certain way, if there be no adhesions, but, as the amount of the fluid further increases, compression of the lung follows. With a very large effusion the lung is pushed wholly up and back against the vertebral column, and is changed to an almost bloodless, airless, flat mass. It is, however, possible that the atelectasis of the lung is not caused exclusively by compression from without, but that, after the normal respiratory movements have ceased, a part of the air in the lung may be absorbed by the vessels, or even by the effusion.

We also see the results of the pressure exerted by the pleuritic effusion in the mediastinum and diaphragm, as well as in the lungs. Displacements of the heart arise from the lateral pressure on the mediastinum, which must take place if the pressure in the diseased pleural cavity is equal to that of the atmosphere, for a greater and positive pressure is unnecessary, since a negative pressure prevails on the healthy side.

The downward pressure of the diaphragm, which usually affects both halves of it, although in unequal degree, makes itself manifest on the right by the low position of the liver, and on the left by the downward displacement of the stomach and large intestine. It must be particularly noticed, however, that adhesions may prevent all pressure-displacements which we have mentioned, both of the lungs and of the neighboring organs.

As regards the further changes and terminations of the pleuritic processes, they depend upon the amount and character of the effusion. Favorable cases may result in complete recovery and absorption of the effusion. The fluid contents are taken up directly by the lymphatics of the pleura, and the solid constituents, the fibrine and the white blood-corpuscles, are decomposed, dissolved, and absorbed.

In most of the severe cases, however, an extensive new formation of connective tissue and vessels takes place. The fluid effusion is mostly absorbed, but the pleura itself is thickened and changed—the so-called pleuritic thickening. Very commonly extensive loose or firm adhesions form between the two layers of the pleura—adhesive pleurisy. Spaces may be left between the adhesions, in which the remains of the fluid effusion may be encapsuled—"sacculated pleuritic effusion." In protracted cases, and especially in relapses of inflammation, as a result of phthisis, the pleural membranes may finally reach a thickness of one or two centimetres.

Even in cases with marked thickening final recovery is possible. This always is attended with great cicatricial contraction of the pleura, in which the whole chest-wall is involved. The normal expansion of the lungs and thorax is not restored for months, if at all.

It is largely owing to the nature of the primary disease that extensive pleuritic effusions so seldom fully recover. Hence we often notice that, after temporary improvements, new returns of the pleurisy occur, or serious and usually tubercular diseases of the lungs and other organs.

In old pleural thickenings we sometimes see a deposit of lime-salts, the so-called "pleuritic ossification."

In purulent effusion, too, a final absorption is also possible; but this demands much time, and thick, cheesy masses of pus are often left in the pleural sac. In

most cases of empyema, if there is not timely operative interference, the pus seeks an outlet for itself. It may break through the visceral pleura into a bronchus, and be emptied externally, thus giving rise to a pyo-pneumothorax; but in many cases the pleura seems to be destroyed only superficially, and the pus is pressed into the alveoli as into a sponge, especially by the movements of coughing, and thence reaches the bronchi, without letting the air enter the pleural cavity (Traube). In other cases the empyema breaks externally through the chest-wall—*empyema necessitatis*. The point of rupture is usually found in the vicinity of the sternum, where the chest wall is thinnest. In very rare cases the empyema breaks into the deeper parts of the body, or into the abdominal cavity.

**Course of the Disease.**—We will speak in what follows especially of the course and symptoms of ordinary, apparently primary (*vide supra*), fibrinous or sero-fibrinous pleurisy, the so-called simple pleuritic effusion. What is said of it obtains in large measure in the other forms of pleurisy also. The physical signs, of course, are almost wholly independent of the character of the effusion. As far as the different forms of pleurisy differ clinically, we will mention their peculiarities below.

Only rarely is the onset of pleurisy quite acute and sudden, beginning with a rigor. In such cases we must guard against confusing it with croupous pneumonia. Pleurisy usually begins slowly and gradually. The symptoms, which the patient himself feels, are in many cases to be referred directly to the disease of the pleura. One of the most constant is the pleuritic pain, the stitch in the side. A more or less severe pain comes on in the side at every deep breath, and hence upon any physical exertion; also upon movements of the body, in stooping, coughing, or gaping. Shortness of breath soon appears, and constantly increases. There is often a frequent, dry cough. Besides that, severe general symptoms almost always develop: the patient feels dull, looks pale, and has no appetite. Patients who can endure a good deal often keep at work for a long time, until, after feeling miserable for three or four weeks, they are forced to stay at home and summon a physician. It is very important to know that in not a few cases the general symptoms are much more prominent at the beginning of pleurisy than the local ones. The patient comes to the physician complaining only of weakness, loss of appetite, or headache, and the physical examination is the first thing that shows the presence of perhaps a large pleuritic effusion.

In most of the severe cases the further course is slow like the beginning, but sometimes the severest symptoms, most intense dyspnoea, marked cyanosis, etc., may come on in a short time, owing to a sudden increase of the effusion. On the other hand, in mild cases the symptoms may disappear again in a few weeks, but the objective signs in such cases are generally to be made out for a longer time. The disease ordinarily lasts for at least five or six weeks, and often much longer. Gradual recovery follows, or the onset of some new disease, usually tubercular (*vide infra*).

**Single Symptoms.**—The pleuritic pain, the stitch in the side, is one of the most frequent subjective symptoms. We have previously mentioned that in primary diseases of the lungs, too, as in croupous pneumonia, the stitch in the side is due to the accompanying pleurisy. It is remarkable that the intensity of the pain in no way corresponds to the apparent intensity of the disease. There is often the severest pain in the side when the physical examination shows almost nothing. On the other hand, we often hear a decided pleuritic rub without the patient's complaining of any special pain. Pressure on the chest-wall on the affected side is often very painful. With severe pain we may consider the possibility of an invasion of the intercostal nerves by the inflammation. We have never observed cases, like those described by some authors, of "crossed pleuritic pain"—that is, cases where the pain is localized on the side not affected.

**Cough and Expectoration.**—The cough is probably directly excited by the disease of the pleura. We often find the pain in the side, and also the cough, brought on by a deep inspiration. Expectoration is entirely absent in uncomplicated pleurisy, or it is scanty, and consists simply of mucus. Much expectoration always means a pulmonary complication. A large amount of purulent sputum is evacuated if a purulent effusion breaks into the lungs (*vide supra*).

**Dyspnœa.**—The respiration is usually shallow, and consequently frequent, because of the pleuritic pain. In every large effusion which prevents respiration in one lung the dyspnœa becomes more severe, and may, with very extensive effusions, reach the highest degree of orthopnœa. The stronger the patient was before the disease, and the more rapidly the effusion develops, the more severe, as a rule, is the dyspnœa.

**Fever.**—Most severe pleurisies are associated with fever, but its height is not very great, so that it quite rarely reaches 104° (40° C.). The fever has no typical course. In cases with an acute beginning it is sometimes quite continuous, or slightly remitting at first. If improvement takes place, the fever goes down in about two or three weeks by lysis, so that this part of the temperature curve may be precisely like the period of defervescence in typhoid.

In the more protracted cases the fever gradually becomes more remitting, varying between 100° and 101° (38°–38.5° C.), and it assumes more and more the form of hectic fever. The longer the evening rise of temperature lasts, the more we are justified in suspecting tuberculosis. In empyema we see a higher, irregular fever, sometimes associated with severe chills.

The pulse is constantly rapid, up to 100 and over. In all severe cases the strength and tension of the pulse are much diminished. Irregularity of the pulse is not infrequent. All these changes are probably due in great part to the pressure of the effusion on the heart and large vessels. Lichtheim has discovered experimentally that the compression of the vessels in the compressed lung does not lower the arterial tension.

**General Symptoms.**—Pleurisy is almost always associated with a pronounced general malaise, muscular weakness, and dullness. The patient is pale, and often markedly cyanotic in cases with much disturbance of respiration. There is great emaciation if the disease is of long duration.

The appetite declines from the outset. There is often occasional vomiting, especially in the first period of the disease. The bowels are usually constipated. Many patients complain of headache.

The condition of the urinary secretion is very important. In every pleuritic effusion the amount of urine is decidedly diminished so long as the effusion increases or remains at the same height. The daily amount is sometimes only eight or ten ounces (200–400 c. c.). The urine is also concentrated, its specific gravity being about 1020–1028. Sediments of urates often form. This diminution of the excretion of water by the kidneys is largely the result of the diminished arterial pressure. An increase of the amount of urine is always a favorable symptom, often the first sign of beginning absorption of the effusion. If a large effusion is rapidly absorbed, the amount of urine may increase to eighty or a hundred ounces (2500–3000 c. c.) daily. The urine, then, of course, is abnormally clear and of low specific gravity.

#### PHYSICAL SIGNS.

**1. Fibrinous Pleurisy—Pleuritis Sicca.**—Simple fibrinous pleurisy sometimes gives rise to no physical signs at all. If it develops as a result of some pulmonary affection, the physical signs present are often dependent upon this alone.

In many cases, however, dry pleurisy may cause marked objective signs. On

inspection, we are struck by the impaired mobility of the affected side on respiration, which is due to the pain caused by breathing. Because of this same tenderness the patient at first often lies on the sound side. Percussion gives no qualitative change of resonance as yet. With the beginning of exudation slight dullness appears, at first almost always in the lower posterior portion of the lungs. Sometimes the resonance becomes tympanitic as a result of retraction of the lung. We can almost constantly make out, especially in the back, that the lower edge of the lung moves less than usual on respiration. Auscultation gives a respiratory murmur that is either qualitatively unchanged or indefinite, but it is always diminished. The peculiar pathognomonic sign of dry pleurisy, however, is the pleuritic friction-rub, that characteristic rubbing, grating, creaking sound, which arises from the sliding of the rough pleural surfaces over each other, and is detected especially in the lateral portions of the thorax. We can hear it both on inspiration and on expiration. It is often jerky, one rub following another after a considerable interval. If we are sure we hear a pleuritic rub, it is direct evidence of the existence of a dry pleurisy, but its absence will not let us exclude pleurisy. The friction-sound must be absent if there are pleuritic adhesions. We can often feel a marked rub by laying the hand on the chest. Sometimes the patient feels it himself, but in other cases he has no sensation of it. We may confound a slight rub with fine crepitant râles. Repeated examinations before and after the patient has coughed usually confirm the diagnosis, since the râles are often changed by coughing.

**2. Pleuritic Effusion.**—Small amounts of fluid in one pleural cavity escape discovery. Physical signs first appear when the amount of effusion reaches eight or ten ounces (200–300 c. c.).

Inspection shows first the more or less marked impairment of motion on the affected side on respiration. If the amount of the effusion is large, there is an evident distention of the affected side in the lower posterior and lateral portions of the thorax. The intercostal spaces are flattened or even a little convex. The nipples and shoulder-blades are farther removed from the median line on the affected side than on the healthy side. The hypochondrium on the affected side is more prominent. In an extraordinarily large effusion on the left side we have seen and felt, in the left hypochondrium, the lower surface of the diaphragm, which was actually arched downward. By direct measurement in severe cases we can make out accurately that the affected side is expanded several centimetres.

With every large effusion there is marked dyspnoea and accelerated respiration. The slight excursions of the affected side on respiration are usually very striking, while the sound side moves so much the more. In this stage of pleurisy the patient often lies upon the affected side, in order to breathe with the healthy lung with as little restraint as possible. With large effusions complete orthopnoea may develop.

The signs due to displacement of the neighboring organs, which are noticeable on inspection, will be mentioned below in the appropriate connection.

Everywhere that a layer of fluid comes between the lung and the chest-wall there is a loss of clearness in the percussion-note. If the thickness of the layer of effusion is five or six centimetres, the resonance seems completely dull or flat. The pleuritic dullness is almost always first made out in the lower posterior portions of the thorax, more rarely in the lower lateral portions. With a slight effusion the height of the dullness is only a few centimetres, but, with much effusion, it rises higher in the back and the lateral portions of the thorax; and on the right, resonance gradually grows dull anteriorly and inferiorly, above the liver. With very large effusions the dullness may begin in front at the second or third rib, or in rare cases even the whole half of the chest, front and back, may

give a totally flat percussion-note. Pleuritic dullness is always attended with a marked feeling of resistance on percussion.

With medium-sized effusions, where the dullness does not extend over the whole back, the upper boundary of the dullness usually forms an oblique line, highest at the vertebral column and thence running obliquely downward to the side of the thorax. We can no more confirm the opposite opinion, which some authors hold, than can Weil and others, yet of course no one can establish a schematic rule. The lower boundary of the effusion can not be distinguished on the right by percussion from the liver dullness. On the left in front and on the side, however, we can often distinguish the dullness of the effusion from the tympanitic resonance of the stomach, and this is of diagnostic value (see the displacement of organs, as given below).

[In moderate effusion without adhesions or pneumonic complications, the line of flatness in the back, the patient being in the vertical position, is lowest near the spinal column, and rises in a curve like the letter S as it passes outward toward the axillary region. The experiments by Dr. Garland, of Boston, with reference to this point are well known. Before attempting to mark out this line the patient should be told to take several deep inspirations, in order to inflate the triangular portion of lung which dips down near the vertebræ.]

The percussion-note above a pleuritic effusion deserves attention. The beginning of pleuritic dullness is almost always relative, gradually passing to an absolute flatness. The pulmonary resonance above the beginning of dullness is usually tympanitic, from retraction of the lung-tissue. We find the tympanitic resonance beautifully distinct in large effusions in the first and second intercostal spaces in front. It is loud and deep, and remains unchanged with the mouth open—Skoda's resonance. With very large effusions, which cause an actual compression of the lung, we sometimes find, in the second intercostal space, a dull tympanitic resonance, which becomes higher on opening the mouth. This resonance arises from the vibrations of air in a large bronchus surrounded by compressed lung—"Williams's tracheal tone." With large effusions we sometimes hear over the retracted lung, in the upper anterior intercostal spaces, a distinct buckram sound—the "cracked-pot sound."

Displacement of the neighboring organs, which is made out chiefly by percussion, forms one of the most important physical signs in pleurisy with effusion.

In right-sided effusions the liver, especially the right lobe, is displaced downward. We find the lower border of the liver dullness extending several centimetres below the ribs. In very large effusions the liver may be pushed down to the level of the umbilicus. The pushing of the mediastinum to the left in large effusions may be recognized upon percussing from the right toward the left, by dullness over the upper part of the sternum, reaching to or beyond the left border of the sternum. The displacement of the heart to the left in the majority of well-marked cases is associated with a displacement of the apex of the heart upward. This is easily explained by considering the position of the heart and the direction of the pressure, which first acts from below. We recognize the displacement of the heart chiefly by the position of the apex-beat, which is seen and felt at or outside the left mammillary line in the fifth space, or often higher, as we have said—in the fourth. Percussion gives a corresponding displacement of the left boundary of the cardiac dullness to the left.

In left-sided effusions the displacement of the heart to the right, which can usually be made out even in moderate effusions, is especially noticeable. Resonance over the lower part of the sternum is diminished, the heart's dullness extends to the right border of the sternum or several centimetres beyond it. In the most marked cases the heart is pushed to the right mammillary line. The displacement

of the mediastinum is also to be made out over the upper part of the sternum, the dullness reaching to the right border of the sternum or beyond. The low position of the diaphragm is made out by a depression of the left, and in marked cases of the right, lobe of the liver. It is an especially important sign, however, that dullness occurs in the zone, about a hand-breadth wide, of normal tympanitic resonance above the left border of the ribs—the "semilunar space" of Traube. The normal tympanitic resonance here comes from the stomach or large intestine. As the diaphragm is pressed downward the pleuritic effusion presses on these organs. The semilunar space is therefore diminished, and finally, with large effusions, there is absolute dullness down to the edge of the ribs.

Changes in dullness in pleuritic effusions may occur with a change of the patient's position, but they may often be absent on account of adhesions. The respiratory displacement of the lower border of the lung is almost always absent.

Auscultation always gives a diminished respiratory murmur over the pleuritic effusion. With a beginning effusion it may sound approximately vesicular, but later it becomes indefinite, hoarse, and finally bronchial, if the larger bronchi remain open for the respiratory current of air. The bronchial respiration sounds distant and low, and has the character of the sharp German *ch*, but in rare cases it also assumes a distinct amphoric tone, so that it sounds almost like a cavernous respiration. The respiratory murmur may finally disappear entirely over very large effusions. Above the upper boundary of the effusion the respiration almost always sounds harsh. Among the adventitious sounds we must mention the pleuritic friction sound, which of course can be heard only at the upper boundary of the effusion, where the two pleural surfaces meet. Moist râles and rhonchi signify a co-existing disease in the lungs. With slight effusions we often hear, on deep breathing, pure crepitant râles on inspiration, as the walls of the alveoli and bronchioles in the atelectatic lung, which were stuck together, are torn apart.

On auscultation of the voice we sometimes hear bronchophony, and sometimes that bleating, nasal sound known as ægophony. Baccelli advanced the theory that auscultation of the whispered voice might be of service in diagnosing the character of the effusion. With a serous effusion we can understand a whisper distinctly through the thorax, but not with a purulent effusion, since theoretically the cell-elements destroy the waves of resonance. This theory holds true in many cases, but by no means in all.

On auscultation of the heart we notice, as a result of its displacement, an abnormal extension of the region over which the heart-sounds are audible. If the inflammation spreads from the pleura to the outer surface of the pericardium, we can sometimes hear an extra-pericardial friction-rub, accompanying both the respiration and the action of the heart.

The vocal fremitus is always diminished over the pleuritic effusion, and in marked cases is entirely absent.

**3. Absorption of the Effusion—Pleuritic Contraction.**—The beginning absorption of the effusion is usually first made evident by the percussion-note in the upper part of the dullness becoming clearer and sometimes tympanitic. The respiratory murmur is also plainer. Where it was bronchial it becomes indefinite and gradually vesicular again. The vocal fremitus is again to be felt. All these improvements take place gradually but slowly. It is usually a very long time before the percussion-note resumes its normal clearness.

The changes in the form of the thorax are especially striking. Only in pleurisy with slight effusion does the somewhat expanded thorax resume its old form without further change. After every severe pleurisy with large effusion there is, during its absorption, a marked contraction of the affected half of the chest. In

cases of moderate intensity the contraction affects only the lower lateral portions of the thorax, in severe cases the upper and anterior portions as well. We find the most marked contractions in children and young persons with a yielding thorax. The circumference of the affected side is much less than that of the sound side. The ribs are pressed together and the intercostal spaces become very narrow. The fossæ are deepened and the nipples and shoulder-blades are drawn nearer the vertebral column, which takes on an abnormal lateral curvature, in which its convexity is directed usually toward the affected side, but sometimes to the sound side. Dullness and diminution of the respiratory murmur and vocal fremitus continue with the contraction of the pleura, but they no longer depend upon the presence of a fluid effusion, but are due to the pleuritic thickening.

The process of marked contraction always lasts for months, or even longer. In favorable cases the contraction of the thorax may be readjusted very much later, often after years. The thickening is absorbed, and the lungs and thorax gradually expand, but in other cases there are extensive adhesions between the pleural surfaces, especially over the lower lobe, which result in a permanent disturbance of respiration. In almost all cases of pleurisy with contractions there arises a vicarious emphysema in the lung on the sound side.

**Complications.**—Peculiar complications of pleurisy are rare. Where such occur they are due either to the primary disease which has led to the pleurisy, or the simultaneous action of the same cause of disease, such as tuberculosis. Hence it happens that we speak of the frequent "complication" of pleurisy with chronic bronchitis or with tuberculosis of the lungs or other organs. It is important to bear in mind that, by a direct advance of the inflammation, the pleurisy may also invade the pericardium, and rarely the peritoneum, through the diaphragm; but we see this extension of the process almost solely in tubercular and purulent pleurisy. We must mention, finally, that we have seen several cases with a large serous effusion, in which an acute hæmorrhagic nephritis occurred. For the paralysis of the arm on the corresponding side observed in some cases of empyema, compare page 538.

#### DIFFERENT FORMS OF PLEURISY.

1. **The Simple Fibrinous or Exudative Pleurisy**, as a result of croupous or extensive lobular pneumonia, often causes but few symptoms in comparison with the primary disease. Recovery is usually complete, but may be much delayed, as in croupous pneumonia.

The so-called primary simple fibrinous or sero-fibrinous pleurisy, which we must regard as a distinctly rare affection, contrary to the generally prevailing opinion, has a like favorable course.

2. **Tubercular Pleurisy.**—In an ætiological sense we must declare the larger part of the ordinary "pleuritic effusions," which clinically seem to be primary to be tubercular. We do not know how far at first the specific anatomical changes of tuberculosis are present, or whether there is always some previous tubercular affection in the lungs or bronchial glands, but the further course of the cases, if we can watch them for years, almost always permits us finally to recognize the tubercular nature of the disease; yet we can not say that phthisis is always the immediate sequel of the pleurisy.

In a comparatively small number of cases do the symptoms of acute tuberculosis, or more frequently of chronic phthisis, appear as an immediate result of the pleurisy, which at that time is usually still present or in the contracting stage. The objective changes of phthisis are evident either in the apex or in the lower lobe of the affected side. The fever continues, the pulmonary affection advances,

the other lung is also attacked, and the disease takes a fatal course under the type of an ordinary phthisis, now more acute and now more chronic.

In other cases acute tubercular affections arise sooner or later as a result of the pleurisy—tubercular meningitis, or general miliary tuberculosis. In other cases still the disease develops under the form of tuberculosis of the serous membranes, to which we will return again in the description of tubercular pericarditis and tubercular peritonitis. We often have to do with a double pleurisy with no evident complication in the lungs. In varying succession are added the symptoms of chronic tubercular peritonitis, with pain, swelling, and effusion of fluid into the abdomen, or the symptoms of tubercular pericarditis. Death finally ensues with persistent hectic fever and increasing general emaciation and weakness. The whole affection usually runs a chronic course, lasts for months, and often shows marked remissions and temporary improvements.

In very many instances the pleuritic effusion has throughout an apparently favorable course. After some weeks the fever ceases, the effusion is absorbed, the patient gets up, and is finally discharged as nearly well. Of course, some dullness and retarded motion often remain in the affected side, but even these may gradually disappear. These cases, too, very often turn out in the end to be tubercular. After a longer or shorter period of apparent health, sometimes after the lapse of years, a "new" disease appears—that is, either a return of the pleurisy, a pleurisy on the other side, or some other acute or chronic tubercular affection. In such cases, too, we must look upon the former pleurisy, in an ætiological sense, as tubercular. It is not impossible, however, for even a tubercular pleurisy to recover, and for the recovery to be permanent, if no other organ is at the same time affected by tuberculosis, especially if the lungs remain unaffected.

Finally we must mention the cases where a pleuritic effusion develops secondarily to an already pronounced phthisis. Here too we almost always have to do with a tubercular pleurisy.

The anatomical changes in tubercular pleurisy consist in the ordinary signs of inflammation, and also the presence of the specific nodules of tubercle. The number of tubercles differs very much in different cases. The pleura is in some cases completely studded with miliary nodules, and in others we find the tubercles, at least with the naked eye, only in single spots. The effusion is usually of a sero-fibrinous character. Sometimes it is hæmorrhagic, as the majority of cases of apparently primary "hæmorrhagic pleurisy" are generally of a tubercular nature. The exudation is rarely purulent, and when this is the case it is apparently invariably caused by the simultaneous infection of the pleura with another sort of virus which gives rise to the suppuration.

**3. Purulent Pleurisy—Empyema.**—We have already described the ætiology of empyema, and we have seen that it can be excited only by infection of the pleura with a specific virus which can set up suppuration. The clinical symptoms are usually severe. The fever is higher than in the other forms of pleurisy, but it is irregularly intermittent, and is often associated with chills. There are severe general symptoms besides the fever, such as great dullness, headache, and a dry tongue. We sometimes notice a slight œdema of the chest-wall on the affected side. Otherwise the local symptoms and disturbances are, of course, the same as in the other forms of pleurisy. If the pus is not evacuated artificially, the empyema may finally break externally or into the lungs (*vide supra*). In the latter case a very large expectoration of pus suddenly occurs, and is usually followed by pneumothorax.

**Diagnosis.**—Our chief attention in regard to diagnosis is directed to the distinction between pleurisy and acute or chronic pneumonia, which is not very easy in

all cases. We will therefore briefly contrast the distinctive features as made out on physical examination.

*Inspection.*—A marked distention of the affected side points to effusion; it does not occur in pneumonia.

*Percussion.*—The dullness in pleurisy is complete, and the feeling of resistance on percussion is very marked; in pneumonia, however, the dullness is rarely so marked, and there is often a tympanitic sound. The discovery by percussion of signs of displacement of the neighboring organs is of especial weight, as these signs are always absent in uncomplicated pneumonia, while with few exceptions they can easily be demonstrated in every case of pleurisy where the exudation is at all considerable.

*Auscultation.*—Diminished or suppressed respiratory murmur points to pleurisy, loud bronchial breathing and râles to pneumonia; but we must not forget that in pneumonia auscultation may give the same signs as in pleurisy, if a bronchus is plugged.

*Vocal Fremitus.*—Marked vocal fremitus over dullness is direct evidence of pneumonia, diminished or absent vocal fremitus of pleurisy; but the vocal fremitus may also be diminished in pneumonia if a bronchus is plugged.

Besides the physical signs, we must of course consider the other symptoms—the manner of onset, the course of the disease, the fever, the sputum, the occurrence of herpes, etc.

If we have diagnosticated a pleuritic effusion, the next question is always as to the character of the effusion, because the prognosis and treatment are to a large degree dependent upon this. Although certain well-known ætiological circumstances, and the severity of the fever and the general symptoms, often permit us to suspect the nature of the effusion, whether serous or purulent, the only certain information comes from an exploratory puncture with a hypodermic syringe. There is not the least reason, if the syringe be carefully disinfected and the fluid be cautiously withdrawn, why we should not perform this perfectly safe experiment in all important cases, thus making the diagnosis certain. Besides a macroscopic inspection, a careful microscopic examination of the fluid withdrawn is sometimes of importance. Besides the ordinary constituents—red and white blood-corpuscles, endothelial cells, and cholesterine crystals—we may sometimes find something of special diagnostic significance, like bacteria in septic pleurisy, carcinoma-cells in cancerous pleurisy, etc.

We can not always judge from the beginning whether a pleurisy is tubercular or not; but we should never forget, as has already been affirmed, that in every case of pleurisy, even if it is apparently primary, there is a strong suspicion of tuberculosis. We must observe in particular the general habit and the nutrition of the patient, and inquire into the hereditary predisposition and any previous illnesses. In the further course of the disease persistent hectic fever, slowly increasing emaciation and pallor, fresh relapses, and the onset of pulmonary symptoms, point to the tubercular character of the pleurisy. Every double pleurisy, and every pleurisy associated with pericardial or peritoneal symptoms, leads us most decidedly to suspect tuberculosis. A hæmorrhagic effusion, as we have said, points strongly to tuberculosis. Tubercle bacilli are usually not present in the fluid exuded in tubercular pleurisy, because the tubercular nodules on the serous membrane hardly ever ulcerate.

*Prognosis.*—The prognosis, as regards the immediate danger of the disease, depends entirely upon the severity of the symptoms, and especially upon the dyspnoea. The prognosis, as regards the further course of the disease, depends chiefly upon the nature of the pleurisy. Many secondary and also many apparently primary pleurisies, although extensive, recover completely and permanently

after weeks or months. Unfortunately, we only too frequently have to give a doubtful or an unfavorable prognosis, especially if the tubercular nature of the pleurisy be probable or certain. The prognosis of empyema depends partly upon the underlying disease, but especially upon judicious and timely operative interference. The healing process in empyema may occupy many months, but it may finally be complete. The possibilities of a spontaneous rupture of empyema, internally or externally, have been mentioned above. With incomplete healing, which leaves a pleural fistula, we must fear the appearance of general amyloid disease in various organs.

In rare instances with large effusions sudden death occurs, an event which can not always be explained with certainty. Probably there are different factors in different cases, such as pulmonary embolism, cerebral embolism, sudden cerebral anæmia, weakness of the heart, or the onset of pulmonary œdema.

**Treatment.**—In the beginning of the disease the treatment is purely symptomatic. We try to alleviate the patient's symptoms, the pain and dyspnœa, by local applications, especially by mustard plasters, warm poultices, which are usually more grateful than cold applications, sometimes, too, by dry cups, also by embrocations with chloroform liniment, and, with severe symptoms, by morphine internally or subcutaneously. Unfortunately, we have but few remedies to check the inflammatory process in the pleura. If an ice-bag is well borne, it may be of service. The efficacy of the much-used painting with iodine is doubtful, but it may always be tried if there is a severe pleuritic pain. An iodoform ointment, one to fifteen, or iodoform collodion, perhaps deserves more confidence. If a large effusion has formed, we try to hasten its absorption by diuretics. Acetate of potassium, squills, or boro-tartrate of potassium and sodium\* [tartarus boraxatus, P. G.] may be prescribed. When there is weak action of the heart, infusion of digitalis may be given, alone or combined with diuretics. The attempt has also been made to draw off a large amount of water from the body, and thus to hasten the absorption of the effusion, by prescribing drastic purgatives or such diaphoretics as pilocarpine, salicylate of sodium, and hot packs. The so-called Schroth's treatment serves the same purpose—that is, withdrawing as much fluid as possible from the ingesta—but the last-named methods of treatment generally have the result of exhausting and weakening the patient. We therefore make use of them only rarely. It is very doubtful whether the internal exhibition of iodide of potassium can further the absorption of the effusion, as many physicians believe. Besides the treatment by drugs we must also take care to give the patient sufficient food, in order to prevent the loss of strength.

In many cases the operative treatment of pleurisy (introduced by Trousseau)—the evacuation of the effusion by puncture—is of the greatest importance. Many cases of pleurisy with effusion run a favorable course without it, and we consider it at least superfluous to puncture every effusion without sufficient grounds, but puncture is often one of the most serviceable therapeutic influences at our command. The first and most important indication for puncture is present when the effusion becomes so large as to be directly dangerous to life. As soon as the patient's dyspnœa reaches a dangerous degree, and the cyanosis becomes marked and the pulse weaker, a puncture must be made as a direct vital indication. Where the exudation is of considerable size there may be a very sudden aggravation of the symptoms, so that in such cases one should not wait too long. Trousseau urged that tapping should invariably be performed when the dullness caused by the exudation involves not only the back, but also the whole or nearly all of the anterior wall of the thorax. The benefit of such a puncture is often pronounced.

[\* We would use the simpler bitartrate of potassium.—TRANS.]

The second indication is a too protracted absorption of the effusion. Puncture is indicated if the effusion does not disappear after an apparent remission of the inflammatory symptoms, especially after the fever has gone. We often see the further absorption stimulated by such a puncture. It has been said that, if possible, tapping should be delayed until the fever has ceased, but to us this does not seem at all necessary. We have repeatedly performed paracentesis in febrile cases, whether because of the extent of the exudation, the dyspnoea of the patient, or the duration of the disease; and we have not infrequently observed a speedy abatement of the fever after the withdrawal of the exudation. In early cases, of course, one would not tap unless there were some urgent reason for it.

[There is considerable danger in delaying interference with a large effusion, especially if it has come on pretty rapidly, however comfortable the patient may be. The liability to sudden and fatal dyspnoea under these circumstances is now well recognized.]

As regards the performance of the puncture, we can not here go into all the numerous methods and forms of apparatus proposed. The distinctions are immaterial. The simpler the method, the easier it is to perform, and hence the better it is.

Every puncture must be preceded by an exploratory puncture in order to settle the diagnosis as to the presence and character of the exudation. A medium-sized trocar with a lateral opening, to which a rubber catheter can be fastened, serves to evacuate the fluid. Billroth's and Fräntzel's trocars are useful. The operation can be done with at least equal convenience by means of a hollow needle. Our own experience with the form of needle proposed by Fiedler leads us to recommend it highly, for the point of this needle can not irritate the tissues, and it permits of the removal of any clots of fibrine which may offer obstruction to the flow of liquid. The instruments and the chest-wall at the point of puncture must be carefully disinfected. We usually choose rather a low point for puncture, somewhere in the sixth intercostal space, in the middle or posterior axillary line. The patient sits up in bed, but is held and supported by another person, when it is possible. Before and during the puncture he takes a little strong wine. A small cut of the skin beforehand sometimes aids the insertion of the trocar. In many cases, especially with a large effusion, we can evacuate a large part of the fluid by simple puncture and siphoning, since the prevailing pressure in pleuritic effusions is, with few exceptions, positive, from ten to twenty-five millimetres of mercury. The evacuating tube of the trocar must be previously filled with carbolized water and conducted under a layer of the same into the vessel prepared to receive the effusion. The evacuation of the effusion should always be slow and gradual. Many physicians advise to cease when 1,500 c. c. have been removed, but if the fluid is allowed to escape slowly and everything is going well, this quantity may often be exceeded with impunity in the case of large exudations. While, as we have said, in most instances the exudation may be satisfactorily removed by simple puncture and siphonage, it will sometimes prove necessary to employ aspiration. Hence some physicians invariably do so, and to this there is no objection, even if it is unnecessary. The forms of apparatus most used for this are those invented by Dieulafoy, and Potain. In puncture with aspiration we proceed more slowly and cautiously.

[The necessity for two punctures—one exploratory, the other distinctly operative—does not seem clear. The two can be perfectly combined, a fair-sized trocar or needle being as easy of introduction and producing really no more pain than a very fine one, and being more sure to give results on which reliance can be placed. A preliminary incision through the skin seems also useless, and has never been practiced by the editor in a considerable experience with these cases. An ordi-

nary Davidson's syringe makes a very satisfactory pump, and can always be obtained. The needle or trocar should be withdrawn immediately as soon as cough comes on, or the patient shows the slightest discomfort due to the removal of the fluid.]

Unpleasant incidents which may cause a cessation of the process are rare. If the patient complains of dizziness and faintness we must stop. Sometimes very severe cough occurs on puncturing, at which we must also stop. Sometimes we see, after the puncture, an abundant expectoration of frothy, serous sputum—"*expectoration albumineuse*"—a kind of pulmonary oedema, caused, perhaps, by a marked perviousness of the walls of the vessels, or by weakness of the left ventricle.

When the process is over, we close the little opening with a bit of sticking-plaster or with iodoform collodion. A regular surgical dressing is scarcely ever necessary.

If the exploratory puncture has shown a purulent effusion, we can first evacuate the pus by puncture, if the vital indication exists. But a permanent cure from tapping is exceptional. The pus almost always reappears. Empyema is like an abscess, which can not be cured until a permanent, free exit for the pus has been provided; hence drainage of the pleural cavity must be provided for after the empyema has been evacuated. To this end, therefore, most physicians at present open the pleural cavity in empyema by an incision—"thoracotomy." We incise it by layers in the fifth or sixth intercostal space, outside of the mammillary line. The length of the incision is some two or three centimetres. After the pus has been removed we have an artificial pneumothorax opening outward. The incision may be dilated if necessary, and a long drainage-tube is then thrust through it into the pleural cavity, the external end being prevented from slipping into the chest by transfixing it with a safety-pin. Then an antiseptic bandage is applied, which at first must be changed frequently, as long as there is much secretion. If the pus has a sufficient exit, the fever will subside at once, in an uncomplicated empyema. A fresh rise of temperature almost always depends upon the retention of pus. The point of puncture is soon changed to a good drainage-canal by granulations. We can then take out the tube, clean it, and easily reinsert it. If all goes well, we can gradually shorten the drainage-tube more and more, and finally remove it altogether. The cavity of the empyema has filled with granulations, and there follows a definite healing, almost always, of course, with marked contraction. Many cases do not run so undisturbed a course. If the exit is insufficient, we must sometimes dilate the opening with some blunt instrument, and insert a larger tube. In simple empyema, where the pus does not smell badly, it is unnecessary to wash out the pleural cavity with disinfecting fluids, like salicylic and boracic acid solution, permanganate of potassium, or dilute chlorine-water. Carbolic acid should not be used, on account of the danger of poisoning by it. If the empyema is septic, or if there is from the first a stinking, sanious exudation, it is necessary to wash it out. We must then sometimes make a second counter-opening in the chest-wall in order to get a completely free discharge, and to wash out the pleural cavity well. The details upon this and upon many other special points in the treatment of empyema, and especially upon the resection of a rib, which is sometimes necessary, are to be found in the text-books on surgery. It may be added that in the surgical clinic at Leipsic the pleural cavity was often punctured with an ordinary large-sized trocar, through the cannula of which a drainage-tube was introduced into the chest. The cannula was then removed, and the further treatment was as above described.

In treating the chronic, contracted pleurisies with thickening, but without fluid effusion, methodical respiratory efforts, "lung-gymnastics," are of use. Besides

these we should strengthen the general condition as much as possible. We should advise the patient to breathe deeply, and prescribe cold sponging of the chest daily. Inspiration of compressed air by means of a pneumatic apparatus is often accompanied by good results. Well-to-do patients, who have had a severe pleurisy, should be sent to a suitable climatic health-resort.

## CHAPTER II.

### PERIPLEURITIS.

UNDER the name of "peripleuritis" Wunderlich was the first to describe a rare form of disease, which consists of an inflammation of the connective tissue between the costal pleura and the ribs, and which terminates in the formation of an abscess. Similar cases have since been repeatedly observed, and all were characterized by the lack of any discoverable etiology. There is neither a previous injury, nor a primary disease of the ribs or the pleura. Nevertheless the cause must be sought in an invasion of micrococci, which excite the suppuration. A knowledge of the particulars, however, can only be gained from future investigations. They will determine whether peripleuritis can be regarded as an independent disease or not.

The disease occurs chiefly in men. It usually begins suddenly with a chill, and runs its course with quite a high fever. In pronounced cases the local symptoms have the greatest similarity to those of an empyema, but the greater protrusion of the chest-wall is striking. The ribs are crowded apart by the abscess, and there is often spontaneous rupture externally, scarcely ever into the pleura. Percussion gives no symptoms of displacement of the neighboring organs, a distinguishing point from empyema. It is of diagnostic significance that we can often discover normal lung-tissue containing air below the abscess. The mobility of the lower border of the lung is also usually retained, contrary to what is the case in empyema. Another important sign was first brought to notice by Bartels: the wall of the abscess relaxes on inspiration and becomes tense on expiration. We may also mention that acute nephritis has often been observed among the complications.

From these points we may be able to make the diagnosis during life, at least in many cases. The prognosis is quite unfavorable, but recovery does occur. The treatment can be only operative, and is quite analogous to that for empyema.

## CHAPTER III.

### PNEUMOTHORAX.

(*Pyo-pneumothorax. Sero-pneumothorax.*)

**Etiology.**—Pneumothorax—that is, a collection of air or gas in the pleural cavity—arises, in an overwhelming majority of cases, from the penetration of air into the pleural cavity through an opening in the pleura. The opening may be in the external chest-wall from a penetrating wound of the chest or an empyema operation, or it may be in the pulmonary pleura. Pneumothorax is by far most frequently associated with phthisis, when a cavity lying beneath the pulmonary pleura perforates into the pleural cavity. This is more apt to happen in compara-

tively acute phthisis than in very chronic forms, because the extensive adhesions and contractions in the latter hinder its development. It usually appears in quite far advanced cases, but it may sometimes arise with but slight changes in the lung.

Pulmonary gangrene or abscess, as well as phthisis, may cause pneumothorax by perforation into the pleural cavity. It may also arise from the rupture of an empyema into the lung. In some cases a perforation of the œsophagus or stomach into the pleura, as in gastric ulcer, has been observed, with the formation of pneumothorax.

The development of this condition from severe injuries, as from laceration of the lung, without injury to the chest-wall, is rare. Forced respiratory movements, associated with physical exertion, seem especially capable of exciting such a process. We have ourselves seen pneumothorax develop suddenly in a previously healthy woman while hanging out her washing, and another time in a young man during very labored rowing. Both cases recovered rapidly and completely.

All the last-named causes, however, are far less important than phthisis. We have yet to mention that in phthisis, too, there is sometimes a definite exciting cause—severe coughing, vomiting, or muscular exertion—which may favor the development of the pneumothorax.

Many authors maintain that, by decomposition of a putrid pleuritic effusion, gas may be produced, and thus we may have pneumothorax; but such an event is extremely rare, if it ever happens.

**Pathological Anatomy.**—On opening the pleural cavity a part of the air usually rushes out, sometimes with an audible noise. We then look into a large cavity filled with air, and find, in total pneumothorax, the lung completely retracted and lying compressed against the vertebral column. If, however, the air fills only a part of the pleural cavity, as a result of extensive adhesions of the pleuræ, we speak of a circumscribed or sacculated pneumothorax. The amount of air contained in the pleural cavity may reach 2,000 cubic centimetres. The pressure which it is under is almost always positive—on an average five or ten centimetres of water.

In the cases of pneumothorax arising from perforation of the pulmonary pleura we can usually make out the point of perforation in the lungs. This is more frequently situated in the upper lobe than in the lower. Sometimes it is already grown over or is covered by a layer of fibrine, and can no longer be found. The opening is usually quite small, but it may reach the size of a ten-cent piece. Left-sided pneumothorax seems to be somewhat more frequent than right-sided.

The pleura itself is only rarely normal. Usually agents of inflammation have entered it with the air, and hence it is found in a state of inflammation. A part of the cavity is then filled with effusion. This is usually wholly purulent—pyo-pneumothorax—or sero-purulent, but it may even be serous or sero-fibrinous—sero-pneumothorax, or hydro-pneumothorax.

The neighboring organs, especially the heart and liver, are found pushed out of their normal position, as in large pleuritic effusions.

**Symptoms and Course.**—The onset of pneumothorax (we speak in what follows especially of pneumothorax in phthisis) is quite often made known by a sudden pain, usually associated with an increase of the dyspnoea and of the general symptoms. There is sometimes collapse. The temperature sinks below normal, the pulse rises to 140 and over. The patient looks pale and cyanotic. He usually sits upright or is in a half-sitting position in bed, either more on the affected side, in order to use the normal lung as much as possible for breathing, or more on the sound side on account of the tenderness. If the pneumothorax has come on as

a result of the rupture of an empyema into the lungs, there is at the same time a very abundant expectoration of pus.

Although in many cases the symptoms mentioned lead to a suspicion of pneumothorax, yet a certain diagnosis can be made only after a physical examination.

Inspection gives a very marked distention of the affected side. The intercostal spaces are stretched out, or even protruded. In some cases, as we have ourselves noticed, there is a marked elastic "air-cushion feeling" on palpating the intercostal spaces. On respiration, the affected side is almost entirely motionless, while the excursions of the other side are the more marked. The displacement of the heart is often evident from the visible displacement of the apex-beat.

Percussion gives over the pneumothorax a remarkably loud, full, deep note, but usually not tympanitic, on account of the tension of the walls. It is especially important to note that this resonance extends beyond the normal limits of the lung on the right down to the seventh or eighth rib, and on the left to the fifth or sixth rib, and sometimes even to the edge of the thorax.

The displacement of the neighboring organs can also be made out by percussion. With right-sided pneumothorax we find the lower border of the liver dullness abnormally low, and the left border of the cardiac dullness pushed over to the anterior axillary line. In left-sided pneumothorax the cardiac dullness is usually entirely absent from its normal place, and is found instead to the right of the sternum. The left lobe of the liver is pushed downward, and we do not find tympanitic resonance in the semilunar space.

Upon auscultation we are struck by the entire absence of respiratory murmur. This is in special contrast to the clear resonance on percussion. In other cases, however, we hear a number of metallic sounds, at least in many places and at many times, which are very characteristic of pneumothorax. First among these is amphoric, metallic respiration. This arises in open pneumothorax (*vide infra*) from the direct passage of the air in and out, but in all other cases it is the ordinary respiratory murmur of the larynx, trachea, and lungs, which has acquired a metallic timbre from resonance in the pneumothorax. In an analogous way arise the metallic-sounding râles ["metallic tinkling"], and the metallic resonance of the cough and voice. Heubner has devised a particularly beautiful and practically important method for demonstrating the metallic sound in pneumothorax. If we strike lightly on a pleximeter with a little rod, usually the handle of a percussion hammer, while we auscult near it—"rod percussion"—we very often hear quite a distinct high metallic sound.

The vocal fremitus over a pneumothorax is usually diminished, but it may be felt in spite of quite a large collection of air.

A number of special physical signs are found if a purulent or serous effusion be added to the pneumothorax. In the first place, the resonance is thereby rendered dull, to a greater or less extent, in the lower parts of the chest. The boundaries of the fluid by percussion show a very evident change with the patient's change of position, because the fluid in pneumothorax can move easily in all directions. Since the form of the air-space left must therefore change, the pitch of all the metallic sounds manifest anywhere must change too, when the patient sits up or lies down—Biermer's change of note. In many cases at every motion of the fluid, excited for example by slightly shaking the patient, there arises a metallic splashing sound, the so-called succussion of Hippocrates.

**Forms of Pneumothorax.**—According to the condition of the perforation during life, we distinguish three kinds of pneumothorax (Weil). We speak of an "open pneumothorax," if the point of perforation remains open, so that the air on respiration constantly passes in and out of the pleural cavity. If the perforation is completely closed, we have a "closed pneumothorax." The third and most fre-

quent form is the "valvular pneumothorax," in which air enters the pleural cavity at each inspiration, but on expiration there is a valve-like closure of the perforation, and thus the air can not escape again; but as soon as the pressure in the pleural cavity increases so that no more air can enter it on inspiration, the valvular pneumothorax becomes closed. In open pneumothorax the pressure in the pleural cavity must be the same as the atmospheric pressure. A positive pressure in the pleural cavity can exist only in a closed or a valvular pneumothorax.

The clinical diagnosis of the form of pneumothorax is not always possible, and has usually no great practical importance. The very loud, metallic, amphoric respiratory murmur, which may be heard in open pneumothorax, must be mentioned, and Wintrich's change of pitch (see page 223) can sometimes be heard in this form. It is worthy of mention that symptoms of displacement of the neighboring organs must also arise in open pneumothorax. The predominant atmospheric pressure here is positive in contrast to the negative pressure in the other pleural cavity, and to the normal negative pressure which previously acted on the upper surface of the diaphragm. A very marked protrusion of the affected side, and great displacement of the heart and liver, however, speak most strongly against an open pneumothorax. Some authors have tried to find a point of distinction for the different forms of pneumothorax in the composition of the gas in the pleural cavity, but the results of chemical analysis are still contradictory. According to Ewald, we find in open pneumothorax not over five per cent. of carbonic acid and about twelve to eighteen per cent. of oxygen; in closed pneumothorax, however, fifteen to twenty per cent. of carbonic acid and ten per cent. at most of oxygen. If in an open pyo-pneumothorax or sero-pneumothorax the point of perforation lies below the level of the fluid, there sometimes arise on every inspiration metallic sounds, since the bubbles of air drawn in rise and come up through the fluid—"the water-pipe sound," "metallic tinkling." A peculiar sipping and short snapping sound on inspiration, heard by us in one case, seems to point directly to the existence of a valvular pneumothorax. Upon change of position of the patient we can often make out Biermer's change of note.

**Course of the Disease.**—In many cases the occurrence of pneumothorax causes such a high degree of respiratory disturbance that death ensues in a few hours or days. In other cases the patient improves, and may feel quite well for a long time in spite of the condition. Usually, of course, the underlying disease, commonly phthisis, leads to death after a longer or shorter period. Pneumothorax may sometimes heal. The healing takes place in this way, that the air is first replaced by a fluid effusion, and then the latter is gradually absorbed, but the air may also be wholly or partly absorbed. It depends upon the origin of the lesion, then, and upon the intensity of the underlying disease, whether the recovery is permanent or not.

**Diagnosis.**—The diagnosis of pneumothorax is usually easy with careful examination, but the symptoms may sometimes be of so little prominence as to excuse overlooking it. It is very difficult and often quite impossible to make a differential diagnosis between very large cavities and a saccular pneumothorax, since both conditions must have in part precisely the same symptoms. We may mention as the chief points in distinction: A cavity is apt to be situated in the apex, pneumothorax in the lower part of the thorax; over a cavity the chest-wall is often sunken in, over pneumothorax it is prominent; the vocal fremitus is usually marked over a cavity, weak over pneumothorax; symptoms of displacement, and also evident succussion, point to pneumothorax.

**Treatment.**—The only remedy which can alleviate the often severe symptoms is morphine. In hopeless cases we may confine ourselves to prescribing this exclusively, both internally and subcutaneously; but in cases where the patient's

previous strength was fairly good, we may try to obtain, by operative interference, an improvement of the symptoms, and finally a complete healing of the pneumothorax. If there is simple pneumothorax without a fluid effusion, we try to remove as much air as possible by aspiration. With a large serous effusion removal of the effusion is indicated, and with purulent effusion either a simple puncture, or, better, puncture or incision with subsequent drainage. The method then is just the same as in the treatment of empyema. We must also state that the above-mentioned improvement or healing in pneumothorax has been repeatedly observed independently of any operative interference.

#### CHAPTER IV.

##### HYDROTHORAX. HÆMATOTHORAX.

1. **Hydrothorax.**—We term the occurrence of a serous transudation into the pleural cavity, independent of an inflammation of the pleura, hydrothorax, or thoracic dropsy. The cause of hydrothorax is in rare cases a local hindrance to the outflow of venous blood or lymph from the thorax, as in compression of the veins or of the thoracic duct by tumors; but in the great majority of cases the hydrothorax is part of a general dropsy, occurring especially in pulmonary emphysema and in cardiac or renal disease. Hydrothorax is often first developed after marked oedema of the subcutaneous cellular tissue and ascites, but it may sometimes be one of the first symptoms of dropsy. It is usually bilateral, but it is often unilateral, or at least much larger on one side than on the other. The pleura itself is normal or else oedematous. We often find it traversed with a network of dilated lymphatics. The serous fluid in hydrothorax is distinguished from an inflammatory serous effusion by the smaller amount of albumen in it, by the scanty number of cell-elements, and by the absence of or the slight tendency to spontaneous coagulation.

The clinical importance of hydrothorax lies in the hindrance to respiration which it causes. As a result of this the hydrothorax may be regarded in many cases, especially in renal disease, as the chief cause of death. The objective evidence of it comes from the physical examination, which must, in general, give the same signs as in pleuritic effusion. We can note only the bronchial respiration from compression in hydrothorax, which is often very loud, and which may even give rise to a confusion with pneumonic infiltration in the lungs. This frequent and very loud respiratory murmur, contrasting with that of pleuritic effusion, is explained by the normal condition of the lungs and the absence of all adhesions. For the same reason, too, the change in the boundary of the dullness, as a result of the patient's change of position, is usually more marked in hydrothorax than in pleuritic effusion. We often hear crepitant râles over the hydrothorax, which arise in the retracted and partly atelectatic lung. The chief factor, however, in distinguishing hydrothorax from a pleuritic effusion is the character of the primary disease if any exists.

The treatment is directed especially to the underlying disease. If we succeed in regulating the heart's action, or in restoring the secretion of urine, the hydrothorax often disappears with the other dropsical symptoms. If the dyspnoea caused by it reaches a dangerous degree, we often see great relief from aspirating the fluid. The nature of the underlying condition, of course, renders the benefit in many cases only transitory.

2. **Hæmatothorax.**—Effusions of blood into the pleural cavity (hæmatothorax)

arise most frequently from traumatic lacerations of blood-vessels, rarely from the bursting of an aneurism of the aorta into the pleural cavity, from erosion of an intercostal artery in caries of the ribs, from the rupture of a cavity into the pleura in phthisis, if it simultaneously opens a blood-vessel, etc. In many such cases a typical exudative pleurisy follows the effusion of blood. The physical signs are the same as in other pleural effusions. Severe dyspnoea may demand the removal of the blood by puncture, or even by an incision.

## CHAPTER V.

### NEW GROWTHS OF THE PLEURA.

THE majority of new growths occurring in the pleura are of a secondary nature. We sometimes find single metastatic nodules of cancer in the pleura after primary carcinoma of other organs, especially of the mammary gland and the lungs, but most carcinomata of the pleura arise from primary carcinomata of the lungs owing to a direct invasion of the pleura by the new growth.

Of the primary new growths in the pleura, only one is of great importance—the endothelial carcinoma, first described by E. Wagner. This develops *de novo*, in a diffuse manner, from a proliferation of the endothelial cells of the lymphatics and the connective tissue. Metastases occur in the lungs, in the lymph-glands, in the liver, in the muscles, etc.

Single secondary nodules of cancer in the pleura cause no special clinical symptoms, but the cases of diffuse cancer of the pleura as a result of primary cancer of the lungs are important, inasmuch as the symptoms of disease of the pleura often quite predominate over the pulmonary disease. The dullness is intense, the respiratory murmur and the vocal fremitus diminished. In one such case we saw a proliferation of the cancer upon the ribs in front so that there was externally a very marked circumscribed swelling. The character of the sputum is the only thing that can give us definite information as to the origin of the new growth in the lungs (see the chapter on cancer of the lungs).

Primary endothelial carcinoma of the pleura runs a course similar to chronic pleurisy. As we sometimes find a co-existing fluid effusion in the pleural cavity, displacement of the neighboring organs may occur. The affection goes on for a long time without fever, or with slight and irregular elevations of temperature. Most cancers of the pleura are associated with severe pain.

The diagnosis of new growths in the pleura can usually be made only, if at all, in the more advanced stages of the disease. At first almost all the cases are regarded as simple or tubercular chronic pleurisy. The diagnosis is founded less upon the physical signs than upon the general course of the disease, the habit of the patient, and the evidence of some metastases in the glands and other organs. In some cases characteristic elements of the new growth can be found by the microscope in the cloudy fluid obtained by an exploratory puncture.

The prognosis is absolutely unfavorable, the treatment purely symptomatic. In endothelial carcinoma we might perhaps try arsenic internally.

CHAPTER VI.

MEDIASTINAL TUMORS.

IN the anterior mediastinum, in quite rare cases, extensive new growths occur, which are of importance on account of their severe clinical symptoms. The point of origin for the tumor is either the mediastinal lymph-glands, or the connective tissue, or sometimes the remains of the thymus gland. In their anatomical character the tumors are almost always sarcomata, usually lymphosarcoma, rarely alveolar sarcoma. They usually occur in youth or middle age, and are somewhat more frequent in men than in women. The special aetiological factors are unknown. In some cases an injury is stated to be the cause of their origin.

The clinical symptoms are usually of a very indefinite nature at first. The patient complains of general languor, headache, pain in the chest, and slight difficulty in breathing, and only gradually do severe subjective and objective symptoms develop in the chest.

The symptoms are in part directly due to the tumor, but in larger part they are symptoms of compression from the gradually increasing pressure of the tumor on a number of neighboring organs.

The pain in the chest, which is located chiefly in the sternal region, and is associated with a marked feeling of oppression, may be very severe. It sometimes shoots into the lateral portions of the chest and into the arms, showing pressure on the brachial plexus.

The dyspnoea may finally increase to an extreme degree. A patient with lympho-sarcoma under our observation could, in the last days of her life, breathe only while standing. The dyspnoea is due to a compression of the heart and lungs, and sometimes to actual stenosis of the trachea or a primary bronchus. Paralysis of the dilators of the glottis may also occur from a pressure paralysis of the recurrent nerves. Paralysis of one vocal cord has been repeatedly observed. In the case mentioned above a marked goitre developed, as a result of vascular stasis, which further increased the dyspnoea by pressure on the trachea. A hydrothorax from local venous stasis may also aid in increasing the dyspnoea.

Pressure on the œsophagus, and disturbances of deglutition due to it, are rare. Pressure on the vagus nerve and the sympathetic sometimes causes anomalies in the rate of the pulse—either marked acceleration or slowing of the pulse. If the sympathetic is involved there is inequality of the pupils. In some cases, by pressure on the tumor, an artificial dilatation of the pupil can be excited at will. By pressure on the vessels, especially on the superior vena cava, the subclavian vein, etc., œdema and cyanosis may arise in the corresponding parts of the body.

Objective examination of the chest gives a marked diffuse prominence of the sternal region in a part of the advanced cases; in other cases this swelling is absent. The discovery of an abnormal dullness in the anterior part of the chest is of diagnostic importance; this usually joins the cardiac dullness on the left, and on the right it extends a varying distance beyond the right border of the sternum. The heart is often pushed somewhat to the left. We heard over the pulmonary artery in our case a marked systolic murmur, caused by compression of the vessel. A dissimilarity of the pulse on the two sides is not infrequent.

The diagnosis of a mediastinal tumor is usually possible in cases with well-marked symptoms, but in other cases it is difficult and uncertain. The differential diagnosis between mediastinal tumors and aneurism of the aorta (*q. v.*) causes especially great difficulty. Tumors may also be confounded with abscesses in the anterior mediastinum.

The prognosis is in all cases absolutely unfavorable. The disease terminates fatally, sometimes after a duration of six months or a year.

The treatment can be only symptomatic. Internally we may try iodide of potassium or arsenic, and externally iodoform ointment. In the last stages of the disease we must try to alleviate the patient's great distress by narcotics.

## CHAPTER VII.

### ACTINOMYCOSIS OF THE THORACIC CAVITY.

BOLLINGER and others have described a peculiar tumor affecting the jaw-bones of cattle, and occasioned by the presence of a special form of fungus, known as the actinomyces or ray-fungus. More recently a class of diseases has been studied in human beings, occasioned by the same fungus (Ponfick, Israel, and others). These diseases may, as in cattle, affect the jaws, the floor of the mouth, and the neck; but in these cases they are mainly of surgical interest. The actinomycotic diseases of the internal organs, however, possess a great clinical importance; and, inasmuch as the lungs and pleura are the most frequently affected organs, it will be well to present briefly here the most important facts which have as yet been learned with regard to actinomycosis. The botanical position of actinomyces has not yet been definitively settled. Cohn and O. Israel regard it as a mold fungus. Boström, on the other hand, classes it with the algae, and namely with the variety

cladothrix. In its growth, the fungus forms small or moderate-sized gray or sulphur-yellow nodules which may be distinguished with the naked eye in the pus of the diseased tissue (see below), and which upon microscopic examination resolve themselves into a tangle of mycelium. It is an especial characteristic that many of these mycelia bear on their ends a club-shaped swelling. These are placed for the most part like radii on the periphery of a nodule, and so surround the entire mass like a circle of rays (see Fig. 28). In nature actinomyces seems to appear especially upon plants, for example upon the beard of spikes of wheat. Thus is explained the frequency of infection in the plant-eating cattle, and a similar direct infection seems occasionally to be possible in man. It is worthy of note that the fungus seems to locate itself often in carious teeth. Thus apparently arises the above-mentioned disease in the buccal cavity; while on the

FIG. 28.—Masses of actinomyces, from JORNE.

other hand, the fungus may be carried further by inspiration into the respiratory tract, or by swallowing into the *primæ viæ*. Of course it may also be directly swallowed or inhaled.

Wherever the fungus fastens itself in the body it occasions first a new growth of granulation-tissue, which has a tendency to break down into a whitish or brownish pasty mass. The brown color is occasioned by the hæmorrhage which

frequently occurs. Very often actinomycosis goes on to suppuration; still, this probably depends upon the influence of pathogenic germs which have secondarily infected the part. Of especial importance is the tendency of the disease to extend from the lungs to the pleura and from the pleura to the peripleuritic connective tissue, and still further to the wall of the thorax. Thus arise not only extensive abscesses and wide-branching fistulous tracts, but also a very characteristic, extremely tough infiltration of interstitial tissue in the affected part. Not infrequently there is at last a perforation reaching the outer surface of the body.

The entire process, as a rule, is slow and insidious, but constantly progressive. The symptoms consist at first in slight thoracic discomfort, pain, cough, and expectoration. Physical examination will often detect changes in the lungs, but the correct interpretation of the signs found is of course at first difficult, if not impossible. The more the disease spreads the greater is the distress. Usually there is hectic fever, which may assume a pyæmic character if there is extensive suppuration. The patient gradually loses flesh, and in repeated instances amyloid degeneration of the liver, spleen, and kidneys has been observed. If a focus breaks into a pulmonary vein, the disease may be developed by metastasis in other internal viscera. Moreover, there may be a direct extension of the disease to the pericardium, or through the diaphragm into the peritoneal cavity.

The diagnosis of actinomycosis is at first difficult. It is established when the characteristic fungus is found in the sputum, but this has occurred in only a few cases as yet. If very extensive peripleuritic and pericostal suppuration has taken place, and the process has spontaneously broken outward or been laid open by surgical means, the demonstration above described in reference to the fungus is easy.

The treatment can only be symptomatic, unless the diseased spot can be reached by operation, and then the treatment becomes surgical. Permanent cure has so far been attained in but rare instances.

## DISEASES OF THE CIRCULATORY ORGANS.

### SECTION I.

#### DISEASES OF THE HEART.

#### CHAPTER I.

#### ACUTE ENDOCARDITIS.

(*Endocarditis verrucosa. Endocarditis ulcerosa.*)

**Ætiology.**—Excitants of inflammation of different sorts, which circulate in the blood, may settle on the endocardium, especially on the valves of the heart, and there give rise to an acute endocarditis. Endocarditis, therefore, in its ætiological relations, is not to be regarded as a single disease; infectious agents of inflammation seem to be its chief, if not exclusive, cause. Lately, pathogenic micro-organisms have been injected into the blood (the streptococcus pyogenes, staphylococcus aureus, and others), and in this way an artificial endocarditis has been set up in animals. The experiments are more apt to succeed if the valves or the inner coat of the vessels have been subjected to some slight injury before the injection, thus promoting the settling of the germs upon them (Orth and Wyssokowitsch, Ribbert).

Of the infectious diseases to which man is liable, it is predominantly acute articular rheumatism in which acute endocarditis is a frequent and important complication. Endocarditis also occurs in certain diseases which are probably allied ætiologically to articular rheumatism, in certain forms of "hæmorrhagic disease," such as peliosis rheumatica, and in chorea. The appearance of endocarditis as a result of gonorrhœa or of gonorrhœal rheumatism is rare, but it has certainly occurred. In the course of the acute exanthemata, too, like scarlet fever and measles, as well as in acute and chronic nephritis, we sometimes notice the appearance of an acute endocarditis.

While endocarditis in the diseases previously named often takes a severe course, in many other infectious diseases—like typhoid, small-pox, and quite frequently chronic phthisis—slight inflammations of the endocardium are often found in the cadaver, which have an anatomical but not a clinical interest. These probably are not directly connected with the primary disease, but are a complication due to the absorption of septic material, the occurrence of this state of things being easily explained by the ulcerative processes of phthisis, the intestinal ulcers of typhoid, etc. We can probably explain in an analogous fashion the origin of the limited endocarditic aggregations which we sometimes find in persons who have died of ulcerative carcinomata, and similar diseases.

Acute endocarditis plays a very important rôle as a complication of severe septic and pyæmic diseases. Beyond a doubt the same pathogenic bacteria are here the cause both of the general sepsis and of the special acute endocarditis; but the latter at times stands so prominently in the central point of the picture

that we may very well give its name to the whole disease, on the principle "*a potiori fit denominatio*."

Finally, we have still to mention the important fact that acute endocarditis quite frequently develops on the soil of an already existing chronic endocarditis—the so-called acute recurring endocarditis. In women, pregnancy and the puerperal state sometimes seem to give the occasion for a recrudescence of the endocarditis; but possibly the old endocarditis merely furnishes a favorable soil for a new infection.

**Pathological Anatomy.**—We usually distinguish an *endocarditis verrucosa*, with the formation of large or small papillary nodules on the endocardium, and an *endocarditis ulcerosa* (*endocarditis diphtheritica*), with ulcerations as a result of the destruction and wasting away of the superficially necrosed tissue. The malignant, invariably fatal form of severe septic endocarditis is chiefly ulcerative endocarditis. Endocarditis verrucosa is the milder form, which is seen especially in acute rheumatism, but we can not draw either a sharp anatomical or a sharp clinical distinction between the two, since malignant cases of endocarditis verrucosa are also observed. It is at present still impossible to give a positive aetiological classification of the different forms of endocarditis.

The endocardial growths are usually situated on the valves, especially on their edges of closure. More rarely we find them on the chordæ tendinæ and on the endocardium of the ventricle and auricle. In the mildest cases they are scarcely as large as the head of a pin, but in severe cases they may increase to quite large warty and glandular masses. Microscopically, the base of the nodule consists of a newly formed vascular tissue, infiltrated with small cells, which on its surface changes to a granular, coagulated mass. This last is formed partly of coagulated albumen, dead cells, and fibrine deposited from the blood, and partly of micrococci. The micrococci are found without exception in all cases of ulcerative endocarditis—having been first discovered by Eberth. In the milder forms of endocarditis verrucosa micrococci have also been found by Eberth, Klebs, and others, but their invariable presence has not yet been established. The endocardial ulcers arise from the destruction of the superficially necrosed nodules. If the thin valve in any place yields to the blood-pressure, we have the so-called acute valvular aneurism. Complete perforation of a valve, and tearing off of fragments of a valve and of the chordæ tendinæ, are also seen.

The great majority of cases of acute endocarditis are confined to the valves of the left side of the heart—the mitral and aortic valves. Endocarditis on the tricuspid valve is seldom seen except as a secondary affection in old cases of heart disease. In a case of acute ulcerative endocarditis in a grown man seen by us, the process was confined exclusively to the tricuspid valve, and there were very many embolic abscesses in the lungs. This may be considered a great rarity. In contrast to the ordinary localization of endocarditis we find foetal endocarditis most frequently in the right side of the heart.

Many other organs may be affected by the endocarditis, through embolism. In the benign endocarditis verrucosa the masses of fibrine deposited on the irregularities of the valve furnish the embolic material. They cause large or small infarctions in the kidneys and spleen, embolic softening of the brain, etc. In the malignant, ulcerative forms, however, large numbers of bacteria get into the circulation at the same time with the necrotic masses of tissue which have been torn off. Here, then, we have to do not merely with simple mechanical obstruction but with infectious emboli. The emboli in ulcerative endocarditis, therefore, either give rise to embolic abscesses in the cardiac muscles, the kidneys, the spleen, the lungs, the retina, etc., or they result in hæmorrhages, especially into the skin, but also into the kidneys, the brain, the retina, and the serous membranes. It is not

yet known why in some cases abscesses are more frequent and in others hæmorrhages. The two, however, may be combined. In general, we may suppose that the development of abscesses is everywhere connected with the presence of bacteria, while hæmorrhages may also arise from toxic influences, for example, fibrine ferment; but changes in the vascular walls caused by bacteria might also give rise to hæmorrhages. Embolic abscesses belong almost exclusively to the severe form of septic endocarditis. Hæmorrhages are seen in this form, and also—without co-existing abscesses—in certain severe forms of endocarditis occurring in the course of acute rheumatism and allied diseases.

**Clinical History.**—Since acute endocarditis is not ætiologically a distinct disease, and since its clinical course is very different in different cases, it seems advisable to us to describe, in what follows, the most important varieties separately; but it must be expressly noted that the separate classes can by no means be sharply defined, and that there are many intermediate forms.

1. *Slight endocarditis verrucosa* is quite frequently found in the cadaver, without the slightest signs of any affection of the heart during life. The little papillary excrecences on the valves of the heart in phthisis, and carcinoma, whose ætiology has been explained above, are to be classed under this head.

2. The typical form of *benign acute endocarditis* is most frequent, clinically, in the course of acute articular rheumatism. It is much rarer in other infectious diseases (*vide supra*). In rare cases its appearance has been noticed as an apparently primary disease.

It is only rarely associated from the outset with subjective symptoms, like pain in the cardiac region, palpitation, and dyspnoea. It is usually first discovered on physical examination of the heart. The impulse of the heart in many cases is abnormally strong and diffuse, the pulse is accelerated, but strong, often somewhat jerky (*pulsus celer*), and usually regular, but sometimes a little irregular. Percussion at first shows no deviations from the limits of normal dullness. On auscultation, we hear at the apex, more rarely at the base, a loud blowing, systolic souffle. Diastolic murmurs are rare in acute endocarditis. The pulmonic second sound is often accentuated. But the physical signs in the heart are only slightly marked in many cases of acute endocarditis. This is understood if we remember that the occurrence of a heart-murmur depends wholly on the localization of the endocarditis, on the development of some valvular insufficiency, etc.

Besides the direct symptoms pointing to the cardiac affection, the onset of an acute endocarditis is often, but not always, associated with fever, or, if fever be already present, with an increase of it, and of the general disturbance. Embolic processes may occur in the brain, the spleen, the kidneys, and the extremities, but they are comparatively rare. Sometimes a pericarditis develops as a result of the endocarditis (*vide infra*).

It is hard to make any accurate statements as to the duration of this form of endocarditis. The physical signs may last for days, or for several weeks. Complete recovery is possible, but in the majority of cases this variety passes into chronic valvular disease of the heart.

3. *Malignant, non-septic form of acute endocarditis* ("rheumatoid endocarditis" of Litten). In many cases this form is perhaps only a quantitative increase of the preceding form, but in other cases it is probably distinct from it ætiologically. The severe general infection is usually quite prominent here, and the disease resembles in many particulars grave septic endocarditis. The objective signs in the heart are the same as in the preceding form, but more intense and extensive. The subjective symptoms in the heart, like palpitation and distress, may be quite pronounced, but they may also be almost wholly absent in this form. The general condition, however, is usually bad. There is sometimes high fever with

an irregular or intermitting course, but in many cases the fever is remarkably low in spite of quite severe constitutional symptoms.

The constitutional infection is very often manifested in these cases by the appearance of small or large hæmorrhages in the skin, sometimes in the mucous membranes, as in the conjunctiva and the soft palate, and rarely in the retina. Secondary articular swellings often develop; they are always of a serous character, and never purulent. Renal hæmorrhages and acute hæmorrhagic nephritis are quite frequent. Large emboli may also occur in the different organs in this as in every other form of endocarditis.

The duration of the disease extends over many weeks. In severe cases death ensues with a gradual aggravation of the general condition, and often with severe cerebral symptoms, like stupor and delirium. In milder cases, however, the patient may finally get well.

Regarding the occurrence of this form, we see it most frequently in acute articular rheumatism; also, in rare cases, in gonorrhœa, where it comes on some three or four weeks after the beginning of the urethral affection; also in nephritis, chorea, peliosis rheumatica, etc. The apparently primary cases of this sort usually belong to the recurrent form of acute endocarditis.

4. *The recurrent form of acute endocarditis* consists of an acute increase of the endocardial process, brought on by some exciting cause, in a patient already suffering from chronic endocarditis. The acute disease may show all the gradations from the mildest to the severest. The mild cases often run their course without any special symptoms. To this form we must probably often refer the more or less temporary elevations of temperature which we often see in patients with chronic valvular disease of the heart. In rarer cases the recurrent endocarditis comes on quite suddenly in the form of a severe acute attack. This sometimes seems to be clinically a primary, independent disease, especially if the previous chronic heart disease has up to that time caused no special symptoms. The patient has general malaise, headache, chills, and fever. The last may be quite high— $104^{\circ}$  ( $40^{\circ}$  C.) and over—or moderate, varying between  $100^{\circ}$  and  $102^{\circ}$  ( $38^{\circ}$ – $39^{\circ}$  C.), or it may be entirely absent. In many cases it is intermittent, when the return of fever is often associated with a chill. The symptoms in the heart may be quite pronounced, but in this form, too, they may be obscure and indefinite. In the further course of the disease we meet with cutaneous hæmorrhages, retinal hæmorrhages, articular swellings, large renal hæmorrhages, or typical hæmorrhagic nephritis—in short, just the same general type of disease as in the other malignant forms of acute endocarditis. The course is rarely rapid, and often lasts for weeks. Severe cases almost always end fatally.

5. *The severe septic ulcerative endocarditis* has already been described as a complication of a general septic disease. We therefore refer to the appropriate chapter (see p. 108) for all particulars. Septic endocarditis is probably entirely distinct ætiologically from the forms so far described, and is manifested by quite a rapid fatal course, with severe typhoid or pyæmic symptoms. It is characterized anatomically, apart from the cardiac affection, by the appearance of metastatic abscesses in the various organs, but in many cases, as we have said, abscesses and hæmorrhages are combined.

**Diagnosis.**—The diagnosis of an endocarditis, coming on secondarily in the course of articular rheumatism and other diseases, can be made only by a physical examination of the heart. We must therefore give constant attention to the condition of the heart in diseases which we know may give rise to endocarditis.

The diagnosis of the malignant form of endocarditis often causes great difficulty, especially if the patient is not seen until the later stages. It is confused with typhoid, meningitis, or acute miliary tuberculosis. Examination of the heart

may furnish evident signs, but, as we have said, not invariably. Of the other symptoms the cutaneous and retinal hæmorrhages are of special diagnostic importance, since they are very much rarer in the other diseases just named. The acute hæmorrhagic nephritis, too, in connection with the other symptoms, is, at least to a certain degree, characteristic of malignant endocarditis. The course of the fever is of diagnostic value only when it is decidedly intermittent. A careful search for some ætiological factor is very important for diagnosis in all cases.

**Prognosis.**—In the description of the course of the disease we have already mentioned the prognosis of the different forms. The severe cases of acute endocarditis, some of which are complicated by the presence of an underlying affection, usually, and the cases of severe septic endocarditis always, end fatally. In mild cases recovery is possible, but the process of repair is often so incomplete that chronic valvular disease of the heart develops from the acute endocarditis.

**Treatment.**—The chief requisite in the treatment of every endocarditis is as complete rest as possible for the patient. If ice is well borne, the continuous application of an ice-bag to the cardiac region is of service. Digitalis may be indicated under some circumstances with a weak and irregular action of the heart, but on the whole this remedy is not often used in acute endocarditis. With severe local symptoms, like oppression and dyspnoea, we prescribe mustard plasters and small doses of morphine, and in some cases local blood-letting. Weakness of the heart is to be combated by stimulants—wine, camphor, and ether.

The treatment is also to be directed against the primary disease, although we can rarely succeed in influencing the endocarditis in this way. In articular rheumatism especially, which is the most frequent cause of acute endocarditis, salicylic acid is unfortunately almost wholly powerless against the endocarditis.

In the severe forms of endocarditis the treatment can be only purely symptomatic, and we try to keep up the patient's strength as much as possible. The exhibition of large doses of salicylic acid or quinine has usually no result, or only a temporary one. In many cases the use of arsenic, kept up for a long time, seems to us to be of service.

[For remarks upon the alkaline treatment of rheumatism, see page 909.]

## CHAPTER II.

### VALVULAR DISEASE OF THE HEART.

(*Chronic Endocarditis.*)

**Ætiology.**—A large number of cases of chronic valvular disease of the heart proceed from acute endocarditis. Hence the frequent statement in the history of heart disease that the patient has had articular rheumatism, once or many times. As a result of the endocarditis, which has its chief seat on the cardiac valves, there is considerable thickening of the valvular connective tissue. Processes of contraction also take place, and also adhesions, and finally in many cases quite marked calcification. All these processes have the necessary result, that such deformed valves can no longer fulfill their well-known physiological functions in regulating the circulation. There follows a disturbance in the circulation of the heart itself, and, as an immediate result of it, a disturbance of the general circulation, the pernicious effects of which must finally be manifested in the whole system.

In quite a large number of cases of heart disease, however, we can not obtain a history of acute endocarditis. We have to do here with an endocarditis which

is chronic from the start, which also leads gradually to thickening, contraction, adhesion, and calcification of the valves. The ætiology of this chronic sclerotic endocarditis is still obscure in many of its relations. The same injurious influences which cause acute articular rheumatism, probably, act on the patient in a chronic manner from the beginning; at least, we not infrequently learn from patients with chronic heart disease, without previous acute articular rheumatism, that in former years they suffered repeatedly from slight rheumatic symptoms, to which they paid but little attention. In typical chronic arthritis deformans, too, heart disease occurs, though not very often. In other cases, however, we must consider the possibility of other injurious influences, partly infectious, and partly, perhaps, of a chemical or mechanical nature. Chronic alcoholism, and also constitutional syphilis, true gout, and immoderate muscular exertion, are the exciting causes which chiefly come to our notice. The chronic heart disease in such cases often develops at the same time with, and from the same causes as, general endarteritis, or atheroma of the vessels. To this we may ascribe the origin of many cases of heart disease in advanced age. The influence of chronic nephritis is not to be disputed in the development of chronic valvular disease. A hereditary predisposition to heart disease is not very frequent, but yet it can be made out with certainty in many cases. We have ourselves seen five members of the same family who have suffered from chronic heart disease, some from pure valvular disease and some from severe so-called idiopathic hypertrophy. Perhaps the very frequent occurrence of heart disease in many families is also connected with a special family predisposition to rheumatic affections, the occurrence of which predisposition can not, in our opinion, be denied. Finally, a small number of cases of heart disease, especially in the right side of the heart, depend upon anomalies of development of the heart—congenital heart disease.

Of 163 cases of undoubted chronic valvular disease which we have collected, 86 cases might with great probability be ascribed to articular rheumatism, while in 77 cases the patients had never suffered from rheumatic symptoms. In part of the last-named cases no definite cause could be ascertained, and in the rest perhaps some one of the factors mentioned above was to be found. A number of women referred their symptoms to previous pregnancies and parturitions. As has also been noted by others, the cases without previous articular rheumatism were more often aortic disease than mitral. Particularly in cases where syphilis was to be looked upon as a probable cause have we almost invariably found the chief changes in the aortic valves.

Valvular disease of the heart occurs at every age of life. The time of origin of most cases, corresponding in part to the occurrence of acute articular rheumatism, falls in youth and middle age, somewhere between eighteen and forty. In the female sex heart disease is somewhat more frequent than in the male.

**General Pathology of Valvular Disease of the Heart.**—Every valve of the heart, in order to fulfill its physiological task, must, on the one hand, open perfectly at the right time in order to furnish a free passage to the blood-current through the appropriate orifice, and must, on the other hand, close firmly and perfectly at the right time in order to make any abnormal backward flow of blood impossible. In both relations the function of the valves may be disturbed by chronic endocarditis, the disturbance being the result of their anatomical changes. If the tips of the valves are shortened on their free edges by contraction, or if the complete unfolding of the auriculo-ventricular valves is hindered by a shortening of their chordæ tendineæ, the closure of the valve can not be complete. At the moment when the closure of the valve is necessary a fissure remains open between its apices. We call this condition an insufficiency of the valve. On the other hand, the valves may lose their capability of free and sufficient separation from one

another, as a result of thickening and calcification of the connective tissue, and also as a result of adhesions of the points of the valves with one another. At the moment when the blood-current should pass freely through the open orifice, the valve remains a stiff, narrow ring, through which the blood must force its way—stenosis of the orifice. The changes in the valves are often of such a sort that they cause at the same time both an insufficiency of the valve and a stenosis of the orifice. The thickening and calcification of the valves in stenosis cause, as a rule, a valvular insufficiency at the same time; but an insufficiency, set up by a contraction of the edges of the valves, may occur without a coincident stenosis of the orifice.

Every valvular disease affects the blood-current first in this way: that a stasis of the blood ensues, beginning at the diseased valve and extending backward against the current. The flow of blood through the pulmonary veins, and also through the veins of the body, is impeded, and the filling of the arterial system is thus diminished. To avoid repetition, we will describe more particularly, in the pathology of the disease of individual valves, the precise circumstances under which this disturbance of the circulation occurs. Every such abnormal distribution of the blood, and the necessary slowing of the circulation, from the increased tension in the venous system on the one hand, and the diminished tension in the aortic system on the other, would soon exert a most pernicious influence on the whole body, if a number of compensatory processes did not develop in the heart itself. We shall see how the disturbance of circulation in disease of each individual valve can be overcome by the increased work of certain definite portions of the heart, and how the heart does in fact respond to these increased demands put upon its working strength. It is one of the wisest contrivances in our organism, that the heart has control of a reserve fund of strength, which comes into action, if need be, in a way to compensate as far as possible for any disturbance of the circulation. This explains why a man with valvular disease of the heart may be almost perfectly well for a long time, while the increased work of certain portions of his heart is able to keep up an approximately normal circulation in spite of the existing valvular disease. We call a heart disease, in which there is at least no marked disturbance of circulation, a compensated heart disease.

The abnormally increased work, which single portions of the heart must perform in every case of disease in order to keep up the normal circulation, leads to hypertrophy of that portion, just as in any other muscle. This hypertrophy does not consist in an increase in thickness of the individual muscular fibers, but chiefly in an increase in number. The whole diameter of the cardiac muscle increases, and thus its capacity for work naturally becomes greater. It goes without saying that increased nutritive processes and a large supply of nourishment for the heart are necessary to bring about such a hypertrophy, by which alone a compensation of the heart disease is possible for any length of time. Hence we find the secondary hypertrophy of the heart absent, or at least only imperfectly developed, in weak people, especially in such as have suffered from some other chronic wasting disease besides the heart disease, like phthisis or carcinoma.

Although the compensatory processes in the heart can prevent for a long time any marked disturbance of the circulation, the already overburdened heart can no longer completely satisfy any additional demands upon it, even in a compensated heart disease. Hence patients with a compensated heart disease are free from subjective disturbance from their trouble only when they take complete bodily rest, while the signs of a disturbed circulation usually become quite apparent on slight physical exertion.

The hypertrophied cardiac muscle can seldom supply permanently the abnor-

mally great drafts made upon its strength. There finally comes a condition of "fatigue," of "cardiac insufficiency." The cause lies either in the increase of the valvular disease, so that the hindrance to the blood-current caused by it can no longer be completely overcome, or in the fact that the nervous and muscular elements in the heart have their function gradually impaired by a disturbance of circulation in the heart itself. In short, in every heart disease the moment may finally come when the capacity of the heart has reached its limit, and hence the compensation of the heart disease ceases. The results of stasis now appear with increasing severity in the different organs, as we shall learn to recognize later on, and the patient finally succumbs to them, unless some intercurrent event puts an end to life.

After these general remarks, which will be understood better from what follows, we will pass on to the special description of the different forms of heart disease and their physical signs.

### 1. Insufficiency of the Mitral Valve.

Mitral insufficiency is one of the most frequent forms of heart disease. It develops in acute or chronic endocarditis of the mitral valve, from contraction of the free edges of the valve or from shortening of the chordæ tendineæ. In rare cases it comes on from partial adhesion of the valves with the walls of the ventricle.

The closure of the mitral valve occurs normally at each systole of the left ventricle. It prevents the return of blood from the left ventricle to the left auricle. If the mitral valve is insufficient and its closure is incomplete, at every systole of the left ventricle a part of the blood is thrown back from it into the left auricle through the open space of the ostium venosum. This abnormal backward wave encounters the blood-current coming in an opposite direction into the left auricle from the pulmonary veins. Since these two opposing currents rebound on each other, and since the backward wave of blood presses through the open space in the mitral orifice, decided vertiginous movements arise in the blood, which are the cause of a loud blowing, systolic murmur in the heart. We hear this murmur loudest at the apex of the heart, corresponding to the laws of conduction in the thorax; yet it usually is propagated so far that it may often be heard at the other cardiac orifices, although weaker. A loud systolic mitral murmur can also be heard sometimes in the back, on the left and occasionally on the right. Only in a few cases do we find the murmur louder nearer the base of the heart than at the apex, corresponding more to the anatomical position of the mitral valve. We often hear the first sound of the heart at the apex besides the murmur, but sometimes we do not. The second sound is often not to be heard at the apex, probably because it is obscured by the relatively protracted murmur.

Since the left auricle, at each systole of the ventricle, receives blood from two sides—its normal quantity from the pulmonary veins, and besides that the abnormal blood-wave from the left ventricle—it becomes much dilated. At the next diastole of the left ventricle the whole amount of blood collected in the auricle under increased pressure pours into the left ventricle through the mitral valve, which is now wide open (supposing a pure insufficiency of the valve without any stenosis). We see, then, that in pure mitral insufficiency the left ventricle must be overfilled during the diastole. The left ventricle must also expel in the following systole an abnormally large amount of blood. Although by this contraction only a part of the blood reaches the aorta in the direction of the normal blood-current while a part pours back into the auricle, the work of the left ventricle is of course excessive. This is the explanation, then, why, in pure mitral insuffi-

ciency, the left ventricle is dilated as a result of its increased filling in diastole, and is hypertrophied as a result of its increased labor. The general arterial tension thus remains approximately normal. It is not increased, since a part of the abnormal amount of blood, which pours out of the left ventricle at every systole, flows backward into the auricle. About the normal amount of blood reaches the aorta, and hence the radial pulse, in pure mitral insufficiency, remains of about normal strength and tension.

The anomalies in the movements of the blood in mitral insufficiency produce still other effects. We have already seen that the left auricle is dilated from its overfilling. It also becomes hypertrophied, so far as its weak muscular structure permits, but it is not in itself capable of compensating for the disturbance which the pulmonary circulation suffers from the mitral insufficiency, for the back current from the left ventricle, and the consequent high pressure in the left auricle, must plainly offer an abnormal hindrance to the flow of blood from the pulmonary veins. This stasis sets back through the pulmonary capillaries and arteries into the right ventricle. This may be recognized, on physical examination, by the change in the pulmonic second sound, which is louder, more valvular, and "accentuated," since the closure of the semilunar valves in the pulmonary artery now takes place under the abnormally high pressure which prevails in the arteries of the lungs. The right ventricle has the task of overcoming this abnormal stasis in the pulmonary circulation. It can overcome the abnormal resistance in the pulmonary circulation by increased work, and as a result it becomes hypertrophied. So long as the hypertrophy of the right ventricle suffices to maintain the normal pulmonary circulation, the stasis extends no farther backward, but in the later stages of heart disease we see the right ventricle becoming paralyzed, and more and more dilated as a result of stasis. The flow of venous blood from the body into the right auricle and ventricle is now rendered more difficult. The signs of venous stasis become manifest: the patient has a cyanotic hue, congestive œdema appears in the face and the extremities, symptoms of passive congestion of the liver, spleen, and kidneys appear, and, in short, there is developed the picture of an uncompensated heart disease.

If we now sum up the physical signs of mitral insufficiency, the different methods of investigation give the following results:

**INSPECTION.**—The cardiac region often seems rather prominent, as a result of the hypertrophy of the heart. This protrusion is most marked in young persons with a yielding thorax. The apex-beat is somewhat displaced toward the left as a result of the hypertrophy and dilatation of the left ventricle, and it is quite marked. Besides that, we often see and feel a diffuse pulsation in the whole cardiac region. In the epigastrium we sometimes see or feel an epigastric pulsation proceeding from the hypertrophied right ventricle. In cases which are no longer perfectly compensated the stasis in the veins of the body is rendered apparent by the general cyanotic appearance of the patient and the marked filling of the jugular veins in the neck. Undulatory or pulsating movements often occur in the latter (see tricuspid insufficiency, below).

**PALPATION.**—This confirms the abnormal strength of the apex-beat, and its displacement to the left. We often feel a systolic thrill at the apex of the heart—a "cat's purr"—by laying the hand flat on the chest. This whirl of blood, which is audible as a murmur, may be perceived as a fine tremor of the chest-wall.

The radial pulse is quite strong and usually regular. The sphygmographic tracing of it gives nothing characteristic in mitral insufficiency.

**PERCUSSION.**—This usually gives at first only a moderate increase of the heart's dullness to the left, and a little upward, but in the later stages there is at the same

time an increase of the heart's dullness to the right, caused by hypertrophy and dilatation of the right ventricle. The whole area of cardiac dullness may finally extend two fingers' breadth beyond the right edge of the sternum, and to the left it may reach the mammillary line, or even pass beyond it.

AUSCULTATION.—At the apex of the heart we hear a loud, quite long, pure systolic blowing murmur, limited to the systole, either replacing the first sound or accompanying it. The second sound is often obscure or inaudible at the apex, but the pulmonic second sound is increased and accentuated. Auscultation of the vessels gives nothing characteristic.

## 2. Stenosis of the Mitral Orifice (Mitral Stenosis).

Mitral stenosis often develops in chronic endocarditis of the mitral valve, as a sequel to a previous insufficiency. The valve constantly grows stiffer and more rigid, and the signs of stenosis gradually predominate over those of insufficiency. Hence we very often find stenosis and insufficiency of the mitral valve combined, but often the signs of stenosis are so much more prominent that we can properly speak of a pure mitral stenosis.

The disturbance which the circulation suffers in mitral stenosis is much greater than in mitral insufficiency. In mitral stenosis the orifice may finally become so narrow that it scarcely admits an ordinary lead-pencil. The influx of blood into the left ventricle is accordingly much impeded. During the diastole of the left ventricle the blood must force its way through the stiff and narrow ring of the mitral valve. Thus irregular vertiginous movements develop in the blood, which, in the majority of cases, give rise to an audible diastolic murmur. In mitral stenosis the left ventricle receives a very small amount of blood. Hence, in mitral stenosis, the left ventricle is usually small, its cavity contracted, and the amount of blood thrown into the arteries with the systole is less than normal. In high degrees of mitral stenosis the radial pulse is weak and small, and, besides that, we often find it irregular (see Fig. 29). If we find a hypertrophy of the left

FIG. 29.—Pulse curve in marked mitral stenosis.

ventricle in marked mitral stenosis, as sometimes happens, for which there is no other special explanation, it is probably always to be referred to a previous insufficiency of the mitral valve.

The hindrance to the flow into the left ventricle in mitral stenosis soon leads to a marked stasis, which extends to the right side of the heart through the left auricle, and the pulmonary veins, capillaries, and arteries. The left auricle is dilated first, and its walls are hypertrophied, but it can overcome only a very small part of the resistance at the mitral orifice. The right ventricle can, by more work, so increase the pressure in the pulmonary vessels that, in spite of the narrowed orifice, an approximately sufficient quantity of blood may pour into the left ventricle. Hence we find in mitral stenosis a very marked hypertrophy and dilatation of the right ventricle. The stasis in the pulmonary circulation, manifest objectively by the accentuation of the pulmonic second sound, has as a result a gradually developing ectasis of the pulmonary capillaries. Thickening of the intima of the pulmonary arteries and veins also usually develops. (See the chapter on brown induration of the lungs.)

The results of physical examination are as follows:

**INSPECTION.**—The whole cardiac region may seem slightly prominent, as a result of the hypertrophy of the heart. The heart's action is usually extended over a larger area, but in pure mitral stenosis the apex-beat is no stronger than usual, though often displaced to the left. We have frequently noticed a marked pulsation in the epigastrium, produced by the right side of the heart. The jugular veins are apt to be prominent, and show the different forms of undulatory and pulsating movement.

**PALPATION.**—This also gives signs corresponding to the more extended action of the heart. We sometimes feel the pulsation of the dilated right ventricle even to the right of the sternum. In some cases we feel a diastolic thrill at the apex of the heart, which alone may almost establish the diagnosis of mitral stenosis. This thrill arises from the same vertiginous currents in the blood which form the basis of the diastolic murmur (*vide infra*). The radial pulse is small in every severe mitral stenosis, and is very often irregular.

**PERCUSSION.**—Percussion gives especially an increase of the heart's dullness to the right, reaching to the right border of the sternum or beyond it. The dullness also often extends farther to the left than normal. This may have its origin in a co-existing hypertrophy of the left ventricle (*vide supra*), otherwise it depends on a dilatation of the right side of the heart so great that the left ventricle is pushed farther to the left and backward by it.

**AUSCULTATION.**—The characteristic auscultatory sign of mitral stenosis is the diastolic [pre-systolic] murmur at the apex. This is never so loud and blowing as the systolic murmur of insufficiency, but it usually sounds more rolling or rippling. It is loudest at the apex, and it is transmitted only slightly toward the base. Since, as has been said, the left ventricle in mitral stenosis is sometimes pushed to the left and backward by the very much enlarged right ventricle, in looking for the murmur we must often go far to the left, in order not to auscult the right ventricle only.

The origin of the murmur is easily explained. In the diastole of the left ventricle the blood-current must force its way through the narrow mitral orifice, whence vertiginous movements arise in the blood, and produce the murmur. Since the blood flowing through the narrow orifice has a current of relatively slight intensity, the murmur produced by it can not be very loud. Even in the highest degrees of mitral stenosis the murmur is often quite low. Not infrequently the murmur comes on in the second half of the diastole—namely, when, by the contraction of the left auricle, the blood-current is hurried through the narrow orifice. We call such a murmur, audible at the end of the diastole only, a presystolic murmur, since it usually passes immediately into the first sound.

It is by no means very rare that the murmur is absent in marked mitral stenosis. If such cases do not come under observation until the last stages of the disease, the mitral stenosis can readily escape recognition. We have ourselves often known the previously distinct diastolic or presystolic murmur in mitral stenosis gradually to disappear with the increase of the heart disease. In these cases the intensity of the blood-current through the narrow orifice becomes so slight that an audible murmur is no longer produced. The sounds that are heard arise probably from the right ventricle.

The first sound at the apex is retained in pure mitral stenosis, and often it is even remarkably loud and valvular, a condition which we usually try to explain by the theory that the difference (the "difference in tension") between the abnormally slight tension of the valve in diastole, in mitral stenosis, and its high tension in systole is relatively great. If insufficiency of the valve co-exists, we may hear a systolic murmur with the first sound or instead of it.

The very marked accentuation of the pulmonic second sound, the result of the abnormally high tension in the pulmonary artery, is almost constant. It fails only in very anæmic, weak people, or in co-existing insufficiency of the tricuspid valve (*vide infra*). The second sound at the base is very often "divided" or reduplicated. The closure of the semilunar valves in diastole does not happen at the same time in the pulmonary artery and in the aorta, on account of the unequal tension in the two vessels, so that consequently the two sounds are heard, one shortly after the other. Although this division of the second sound is particularly frequent in mitral stenosis, it is by no means a pathognomonic sign of it.

Mitral stenosis is one of the severest forms of heart disease. It almost always causes greater subjective disturbance than mitral insufficiency. Hypertrophy of the right ventricle can, indeed, maintain for a time an approximately complete compensation, but the signs of marked stasis in the pulmonary circulation, and further in the veins of the body, are apt to appear quite early. The dyspnoea becomes more marked, and dropsical symptoms gradually arise and cause a fatal termination.

### 3. Insufficiency of the Semilunar Valves of the Aorta.

Insufficiency of the aortic valves is most frequently due to contraction of the free edges of the valves. Tears, perforations, or adhesions of the valve to the wall of the vessel more rarely lead to insufficiency. The cause of all these changes is either an endocarditis affecting the valves, or a general atheroma of the arteries, which gradually invades the valves from the intima of the aorta.

The function of the aortic valves is to close tightly at the time of diastole of the left ventricle, in order to prevent any return of blood from the aorta into the ventricle. If these valves are insufficient—that is, if they do not close perfectly at each diastole—there is a return current of blood from the aorta into the left ventricle. The left ventricle then receives blood during its diastole from two sides: the normal flow from the left auricle, and the blood which comes back from the aorta. These two currents of blood, directed against each other, meet in the left ventricle during its diastole, give rise to a marked vertiginous movement of the blood there, and thus cause a characteristic diastolic murmur.

As a result of the excessive expansion of the left ventricle at every diastole, it finally becomes permanently dilated. Dilatation of the left ventricle therefore forms a constant anatomical lesion in every aortic insufficiency, and is shown not only in the dilatation of the whole ventricular cavity, but also in the very characteristic flattening of the trabeculæ and of the papillary muscles. The abnormally great filling of the ventricle during diastole, moreover, gives rise to increased labor; for the left ventricle must expel an abnormally large amount of blood at each systole, which is of course a sort of task of Sisyphus, since a part of the blood thrown out constantly rolls back into it. The increased labor must always lead at last to a hypertrophy of the left ventricle, which may attain the highest degree seen in any form of valvular disease.

From the facts enumerated we can easily understand the physical signs of insufficiency of the aortic valves.

**INSPECTION.**—Great hypertrophy of the left ventricle often causes a marked protrusion of the whole cardiac region. The very strong apex-beat, displaced downward and to the left, is especially striking. It may usually be seen in the sixth intercostal space, outside the left mammillary line, and sometimes even at the anterior axillary line. Besides that, we often see a marked diffuse tremor of the whole cardiac region.

**PALPATION.**—We can appreciate the heart's action to a still greater extent by

palpation than by inspection. The apex-beat is very resistant, massive, and plainly heaving—that is, the finger or stethoscope applied to the apex is lifted by the beat at every systole. In rare cases a diastolic thrill, corresponding to the diastolic murmur, can be felt over the base of the heart. In two such cases observed by us the murmur had a marked musical character (*vide infra*). The appearances in the arteries are given below.

**PERCUSSION.**—Percussion gives an extension of the cardiac dullness to the left, beyond the left mamillary line and even to the anterior axillary line, caused by the hypertrophy and dilatation of the left ventricle. The upper boundary of the cardiac dullness is normal, or it may extend up to the third rib. The right boundary is in its normal place at the left border of the sternum, but it may also be pushed farther to the right, either because the large left ventricle of itself causes an extension of the whole heart to the right, or because the right ventricle is also hypertrophied. The latter change occurs in pure aortic insufficiency when the compensation is no longer complete, and the stasis extends backward from the left ventricle, through the pulmonary circulation, into the right side of the heart.

It may also be remarked here that, in insufficiency of the aortic valves, the ascending aorta is often considerably dilated by the marked impulse from the amount of blood pouring into it. A moderate degree of dullness is found over the dilated aorta, which may sometimes be made out at the sternal end of the second right intercostal space.

**AUSCULTATION.**—Insufficiency of the aortic valves is characterized by a long-drawn, loud, blowing diastolic murmur, the origin of which has been explained above. The place in which the murmur is heard loudest is not the sternal end of the second right intercostal space, the ordinary point for auscultation of the aorta, but it almost always lies farther to the left. Corresponding to the backward current of blood toward the left ventricle, which begets the murmur, we hear the latter loudest over the upper part of the sternum or even at its left border. In some cases the murmur assumes a marked “musical character”—that is, there is a definite high musical tone, which is due to a tendinous fiber arising from a wearing away of the valve, and set in vibration by the diastole, or to some similar cause. The diastolic murmur is often audible at the apex, but it is faint there. Only in rare cases, and especially when the aortic insufficiency results from acute endocarditis, is the diastolic murmur absent. During the systole there is usually a short systolic murmur heard over the aorta. This may, of course, depend upon a co-existent aortic stenosis, but it is also frequently present in cases of uncomplicated insufficiency of the valves. The explanation is, that at the time of the beginning of the contraction of the left ventricle the reflux of blood in the aorta has not wholly ceased, so that the outgoing blood-current has first to overcome this obstacle. It is easy to see why this should give rise to an audible systolic sound, and also why it should have some influence upon the development of a hypertrophy of the left ventricle (O. Rosenbach). It is very remarkable that, as Traube first pointed out, we often hear the first sound at the apex very obscure and dull, or else a short systolic murmur instead of it. This obscurity of the first sound at the apex is of theoretical interest, because it contradicts the hypothesis that the first mitral sound is a muscular sound. It would be especially inexplicable, on this theory, why the first sound is so obscure in insufficiency of the aortic valves, in spite of the hypertrophied and toiling left ventricle; but if we regard the first ventricular sound as originating in the mitral valve, then, according to Traube, its absence in aortic insufficiency may be explained by the fact that the mitral valve during the ventricular diastole is put in a certain degree of tension by the backward current of blood. The greater tension, which develops during the ventricular systole, does not suffice to produce a sound in

the valves, since the origin of a valvular sound does not depend upon the absolute tension, but upon the amount of its sudden increase. The systolic murmur, often heard at the apex in aortic insufficiency, may depend upon a co-existing true mitral insufficiency, but it is probably often due to a relative insufficiency of the mitral, since the valves, which are normal in themselves, can no longer cause a perfect closure of the left mitral orifice now that the left ventricle is dilated.

**SYMPTOMS IN THE PERIPHERAL ARTERIES.**—Such remarkable symptoms are found in the peripheral arteries in aortic insufficiency that they demand a brief special description. The first striking symptom is the strong pulsation not only of the larger but also of the smaller arteries, even those the pulsation of which is not generally visible. We see and feel not only a strong pulsation in the carotids, but also in the tortuous brachial artery, in the radial, ulnar, temporal, dorsalis pedis, etc. We sometimes feel an arterial pulse in the liver through the abdominal walls.

The rapid decline of the pulse—the *pulsus celer* [Corrigan pulse]—is most characteristic of aortic insufficiency, and is to be felt especially in the radial artery, but also in the femoral, dorsalis pedis, and other vessels. An abnormally large quantity of blood is thrown into the arteries from the hypertrophied and dilated left ventricle; hence the high ascent of the pulse; but since at the next diastole of the ventricle the blood escapes in two directions, into the capillaries and back into the ventricle, an abnormally rapid and deep decline of the pulse follows the high ascent of its wave—a condition which explains the “jumping,” “springing” pulse (*pulsus celer*) in aortic insufficiency. The quality of the pulse may be plainly recognized also in the sphygmographic tracing (see Fig. 30). The abnormal backward wave may even be detected in the capillaries. We often see a marked pallor of the finger-nails at every diastole of the heart in patients with aortic insufficiency—Quinke's capillary pulse.

FIG. 30.—Pulse curve in aortic insufficiency.

The auscultatory phenomena over the arteries are partly connected with the changing conditions of tension of the arterial walls. We very often hear a short, rough, systolic murmur in the carotid. The second sound, which is well known to be the transmitted aortic second sound, is absent. Instead of it we sometimes hear faintly transmitted the aortic diastolic murmur. The sound of the medium-sized and smaller arteries is very characteristic. By applying the stethoscope lightly we hear over the femoral, the brachial, and often over the radial, the ulnar, the palmar arch, and the dorsalis pedis, a marked valvular sound, which is changed by pressure on the artery, especially in the larger arteries, to a loud stenotic murmur. The quicker the pulse, the more certain are we to hear these sounds in the arteries. The double sound in the femoral (Traube's double sound) is quite a frequent phenomenon, about the origin and significance of which there has been much discussion of late years. The double sounds either follow each other shortly, so that the first seems something like a preparatory blow for the second, or they are separated from each other by a longer interval, like the two sounds of the heart. Traube explained the origin of the first sound by the sudden

tension of the vessel-wall, as in the simple femoral sound, and the second sound by the sudden relaxation of it. Friedreich has pointed out in regard to this that, in co-existing tricuspid insufficiency, a sound may also be produced in the femoral vein by tension of the venous valves. The double sound in the femoral may probably have different causes of origin. It is, of course, by far the most frequent in aortic insufficiency, but it has also been repeatedly observed in other forms of heart disease, as in mitral stenosis. The so-called Duroziez's double murmur in the femoral is more rare, and it is noticed almost exclusively in aortic insufficiency. This is when we hear, by pressing the stethoscope on the femoral, two murmurs plainly distinct from each other, of which the first comes from the passage of the systolic blood-wave, and the second from the passage of the abnormal backward wave coming from the periphery of the vascular system through the artificially contracted vessel.

Aortic insufficiency is in so far a comparatively favorable form of heart disease for the patient, that it may be almost perfectly compensated for years by hypertrophy of the left ventricle. Many patients with moderate aortic insufficiency feel perfectly well, and are even capable of quite hard work. They have not the slightly cyanotic hue which almost all patients with mitral disease have, but they have a normal or even a pale complexion. If, however, the signs of disturbed compensation once appear, the severest sequelæ may develop quite rapidly in aortic insufficiency. The left side of the heart can no longer satisfy the abnormally great demands upon it. Hence the stasis of the blood sets backward through the pulmonary circulation and into the veins of the body. The difficulty in breathing becomes marked, œdema appears, and the patient dies with the symptoms of general dropsy. We will speak more fully below of certain intercurrent events in aortic insufficiency, such as cerebral hæmorrhage and pericarditis.

#### 4. Stenosis of the Aortic Orifice.

Except for the mild forms of aortic stenosis, which often come on with aortic insufficiency, aortic stenosis is a rare disease. It arises from marked thickenings and calcifications, and especially from adhesions of the aortic valves to one another. The stenosis may become so considerable that the orifice is finally reduced to a mere fissure, through which the left ventricle must force the blood at its systole. The vertiginous movements thus arising in the blood produce a loud systolic murmur. The left ventricle is compelled to do greater work in consequence of the increased resistance of the aortic orifice, and hence becomes hypertrophied. Since it demands more time to drive its contents through the narrow orifice than it does under normal conditions, we often find in aortic stenosis a marked slowing of the pulse, but the pulse, as we can conceive, is small, and the artery feels contracted and hard.

*Inspection and Palpation.*—On physical examination of the heart we find the apex-beat displaced outward, corresponding to the hypertrophy of the left ventricle, but nevertheless it is by no means very strong; it is even sometimes remarkably weak, which condition is explained in part by the slower contraction of the ventricle, and in part by the absence of the backward impulse (compare the Gutbrod-Skoda theory of the heart-beat).

*Percussion.*—Percussion gives an extension of the heart's dullness to the left. The right ventricle is also dilated and hypertrophied to a moderate degree in the later stages, if the stasis extends backward through the pulmonary circulation.

*Auscultation.*—On auscultation, we hear over the aorta a very loud "sawing," long-drawn, systolic murmur, which is usually transmitted to the right, corresponding to the course of the aorta, in distinction from the diastolic murmur of

aortic insufficiency. It is usually to be heard loudest at the sternal end of the second right intercostal space, but it is audible to a lesser extent over almost the whole heart. It is usually quite loud over the carotids. The aortic second sound is feeble, or not to be heard at all. With co-existing insufficiency of the valve it is replaced by a diastolic murmur.

The character of the pulse has already been mentioned. The pulse is small, and is sometimes in noticeable contrast with the strength of the apex-beat; in compensated cases it is regular and often slow, to a slight or sometimes to a great degree. The sphygmographic tracing (see Fig. 31) gives a low wave, and a comparatively slow rise and fall of the curve.

An aortic stenosis of a mild degree may be quite well borne by the patient for a long time. In stenosis of a higher degree we sometimes notice peculiar symptoms, which probably must be referred to anæmia of the brain, especially attacks of dizziness and faintness. Epileptic attacks have even been observed. In other respects the same disturbances of compensation finally appear, as in all other

FIG. 31.—Pulse curve in stenosis of the aortic orifice.

forms of valvular disease. The course of the disease is more unfavorable than that of aortic insufficiency, but, on the other hand, it is more favorable than that of mitral stenosis.

### 5. Insufficiency of the Tricuspid Valve.

Insufficiency of the tricuspid valve is extremely rare as an independent disease of the heart, but a secondary insufficiency of the tricuspid is quite frequent, and is therefore of practical interest, as it complicates other already-existing valvular diseases in the left side of the heart. It arises either from a secondary endocarditis affecting the tricuspid, in quite an analogous manner with mitral insufficiency, or it is a so-called relative insufficiency. This name we give to that form of insufficiency which develops when the edges of the tricuspid valve, normal in themselves, at last fail to meet one another, from the increasing dilatation of the right ventricle.

The necessary result of tricuspid insufficiency is, that in every systole of the right ventricle a backward current passes through the open tricuspid orifice into the right auricle, and thence into the veins of the body. The tricuspid insufficiency ensuing in other forms of heart disease must therefore increase the stasis in the veins of the body, and is thus far an unfavorable complication. It has a compensatory significance only as it affords relief to the pulmonary circulation. Since a part of the blood passes back from the right ventricle into the veins, less blood than usual must reach the pulmonary arteries. The decrease in tension thus produced in these arteries makes itself apparent on auscultation, since the accentuation of the pulmonic second sound in valvular disease of the mitral orifice diminishes when tricuspid insufficiency takes place.

That tricuspid insufficiency must result in a hypertrophy of the right ventricle is explained in just the same way as the hypertrophy of the left ventricle in mitral insufficiency, from the increased influx of blood at increased tension into the right ventricle during diastole; but this effect of tricuspid insufficiency can rarely be made out in any individual case, since the right ventricle is usually already hypertrophied as a result of the disease in the left side of the heart.

The most important symptom from which we can diagnosticate tricuspid insufficiency is the venous pulse. The cause of this is the backward wave of blood produced at each systole of the right ventricle. So long as the venous valve above the *bulbus jugularis* is closed, we usually see only a "bulbar pulse," but very soon this valve also yields to the continued impulse of the blood, and then a strong, purely venous pulse is visible along the whole course of the jugular vein up to the vicinity of the mastoid process. The contraction of the right auricle very often causes a decidedly weaker elevation of the vein, which just precedes the marked pulsation caused by the ventricular systole (anadictotic venous pulse). On account of the straighter course of the right innominate vein, the jugular venous pulse is often stronger on the right side than on the left. We must state, however, that the jugular venous pulse is not an absolutely certain sign of tricuspid insufficiency, since it may arise in hypertrophy of the right side of the heart without any insufficiency of the tricuspid, from the closure of the valves.

If there is pulsation in the bulb of the jugular vein and the jugular valve is still capable of closing, a low, audible, venous, valvular sound may be produced by its closure. A sound may also arise in tricuspid insufficiency, as has been already said, from the tension of the valves in the femoral vein. A visible pulsation in the larger veins of the extremities is very rare, but in tricuspid insufficiency we quite frequently feel a venous pulsation of the liver. This may be quite apparent even in many cases where the jugular venous pulse is absent, because the veins in the liver are without valves.

Auscultation over the right side of the heart gives a systolic murmur in insufficiency of the tricuspid, arising from the regurgitating blood-current. This may be heard loudest over the lower part of the sternum, or at the sternal end of the right fifth rib. The significance of this murmur in diagnosis, however, is impaired by the fact that it can not always be separated from the systolic mitral murmur that often co-exists.

#### 6. Stenosis of the Tricuspid Orifice.

Stenosis of the tricuspid orifice is an uncommonly rare disease, and hence it is without practical significance. It has usually been observed, up to the present time, as a congenital form of heart disease, almost always combined with other anomalies of development in the heart.

The physical signs of tricuspid stenosis can easily be constructed theoretically. The first result must be a marked dilatation of the right auricle, and the occurrence of a diastolic or presystolic murmur over the right side of the heart. From the rarity and complex character of the cases, however, we have so far seldom had an opportunity to confirm these theories at the bedside.

The prognosis of this form of heart disease is very unfavorable, since a long-continued compensation by increased labor on the part of the right auricle is scarcely conceivable.

[Seventy cases of tricuspid stenosis have been collected by Bedford Fenwick, whose analysis affords good grounds for thinking that the lesion is often acquired. In fifty per cent. of the cases there was a clear history of rheumatism, and nearly all of the patients were more than twenty years of age at the time of death.

This lesion is never found alone, but invariably combined with mitral stenosis; all but eight of the cases were in women. Fenwick thinks that the influence of sex lies in the less onerous nature of the work of women than of men, the granulating edges of the valves being kept more in apposition, thus healing with adhesion and causing obstructions at the orifice.]

### 7. Insufficiency of the Pulmonary Valve.

Insufficiency of the pulmonary valve is also a very rare form of heart disease. It occurs as a congenital anomaly, often combined with other failures of development, or as a disease acquired after birth. The anatomical changes in the valve, which lead to insufficiency, are precisely analogous to those which cause insufficiency of the aortic valve.

The physical signs of this form of valvular disease consist chiefly of a marked dilatation and hypertrophy of the right ventricle, to be made out by percussion, and of a loud diastolic murmur over the pulmonary valve. These signs are explained in just the same way as the precisely analogous signs in the left ventricle in aortic insufficiency.

In general, pulmonary insufficiency, like aortic insufficiency, seems to be compensated quite well for a long time by hypertrophy of the right ventricle. In many cases a co-existing patency of the foramen ovale also seems to be of favorable influence, so far as it lessens the stasis in the right auricle and the veins of the body, while it renders easier the filling of the left ventricle.

### 8. Stenosis of the Pulmonary Orifice (Pulmonary Stenosis) and the other Congenital Diseases of the Heart.

**1. Congenital Pulmonary Stenosis.**—While the stenosis of the pulmonary orifice acquired in later life is so rare that it has only a slight practical significance, the congenital pulmonary stenosis is of far greater importance. It is, on the whole, the most frequent of the congenital forms of heart disease. Its origin is to be referred either to an endocarditis of the pulmonary valves during foetal life, or to anomalies in the development of the heart. The stenosis is often situated not merely at the pulmonary orifice itself, but farther back in the conus arteriosus, which seems to be narrowed by the formation of myocardial cicatrices. The pulmonary artery is often also narrowed as a whole. In the majority of cases we find, in addition, other anomalies of development in the heart, especially patency of the foramen ovale, great defects in the ventricular septum, and, in about half the cases, patency of the ductus Botalli, etc.

The symptoms of congenital pulmonary stenosis sometimes appear soon after the birth of the child. The first thing that strikes us is the marked cyanosis, which is constant, or else comes on with crying, or with movements of the body. Many children, however, reach a fair age, five or ten years, but rarely more. In some cases the heart disease may be so perfectly compensated that the child may be comparatively well for a time, and severe disturbances may not appear for several years.

As a rule, children with congenital pulmonary stenosis present a very striking appearance. The cyanosis is especially noticeable in the face, the lips, the nose, and the hands and nails. The parts mentioned feel cool. The eyes are often somewhat prominent, and there is a slight oedematous swelling about them. The peculiar club-like thickening of the terminal phalanges of the fingers and toes, a result of stasis, as seen also in many cases of bronchiectasis, is very characteristic. The nails also present a characteristic claw-like curvature.

The whole development of the child is remarkably retarded. The muscles and fatty layer are slight. The gums are sometimes very spongy and disposed to bleed. In severe cases the child suffers from faintness, vertigo, etc.

On physical examination of the heart, we usually find the cardiac region rather prominent. Percussion gives an increase of the heart's dullness, especially toward the right. This extension of the dullness is due to the hypertrophy of the right

ventricle, which must arise in the same way as hypertrophy of the left ventricle in aortic stenosis. On auscultation, we hear a loud systolic murmur, which is perceptible over the whole heart, but which has its greatest intensity at the sternal end of the second left intercostal space. The eddies of blood, which produce the murmur, may also often be felt by the hand as a systolic thrill. In some cases, however, we miss the murmur in pulmonary stenosis, just as in mitral stenosis. The pulmonic second sound is weak or inaudible, or it is replaced by a murmur if there is also insufficiency of the valve.

The course of congenital pulmonary stenosis is always unfavorable. As has been stated above, only a few children get beyond the age of fifteen years. Death ensues, either with general disturbances of compensation evidenced by dyspnoea and dropsy, as in every other form of heart disease, or from complications. Among the latter, we may mention especially the very frequent development of phthisis.

**2. The Remaining Congenital Lesions of the Heart.**—Inasmuch as other congenital lesions than pulmonary stenosis have but slight clinical importance, we will limit ourselves here to a brief review of the same.\*

(a) Patency of the foramen ovale is a comparatively frequent lesion, whether alone or combined with others. Physical signs are mostly absent. In a few cases a presystolic murmur has been heard. When mitral insufficiency co-exists with a patent foramen ovale, venous pulsation may be caused.

(b) Defects in the septum between the ventricles. These are most frequently situated in the posterior section of the anterior septum, and they likewise are associated with other anomalies, such as abnormal distribution of the arteries, pulmonary stenosis, or defects in the septum between the auricles. Sometimes the patency of the septum gives rise to a systolic murmur, but a diagnosis of the condition during life is scarcely ever possible.

(c) Persistence of the ductus Botalli. Inasmuch as this contributes blood from the aorta to the pulmonary circulation the pressure in the latter is raised, hence there is to be observed accentuation of the second pulmonic sound and hypertrophy of the right ventricle. There is sometimes also a loud systolic murmur.

(d) We have already spoken of congenital stenosis of the tricuspid valve. Congenital narrowing of the mitral valve and of the aortic valves may also occur, but they are extremely rare.

### 9. Combined Valvular Diseases of the Heart.

Although in what has preceded we have dealt with the several forms of valvular disease of the heart separately, in order to present them in a general way, yet in reality combinations of them often occur in great variety. We find especially, as has already been mentioned, stenosis of an orifice co-existing with insufficiency of the accompanying valve; but diseases of two or more different valves are not infrequent, combined in the most diverse manners. The physical signs of these "combined forms of heart disease" may, of course, be inferred from the signs of anomalies of single valves, but the phenomena are often so complicated that the diagnosis of combined heart disease is generally much harder than that of the simple forms. Sometimes the single forms neutralize one another in their action. For example, the left ventricle is usually small in pure mitral stenosis, but, if aortic insufficiency be also present, it is nevertheless found dilated, at

\* A more extensive presentation of the subject can be found in Gerhardt's "Handbuch der Kinderkrankheiten," Band iv, written by Rauchfuss, and in text-books on pathological anatomy—for example, Orth's.

least to a certain degree. The influence of an absolute or relative tricuspid insufficiency on the action of mitral disease, especially the decrease in tension in the pulmonary vessels caused by it, and also the diminished accentuation of the pulmonary sound, have been mentioned above.

In reference to the clinical symptoms of combined heart disease we may say, on the whole, that, in a large number of cases, the disease of *one* valve stands out as predominant in the whole picture of the disease. The other anomalies are only slightly noticeable, and often of later date. Hence, we may find at the autopsies of patients, who during life have shown the symptoms of disease of only *one* particular valve, unimportant changes, like fresh endocarditis, on the other valves, which have been without clinical significance.

#### GENERAL COMPARISON OF THE MOST IMPORTANT PHYSICAL SIGNS IN VALVULAR DISEASE OF THE HEART.

Form of Heart Disease.	INSPECTION.	PALPATION.	PERCUSSION.	AUSCULTATION.
1. <i>Mitral insufficiency.</i>	Strong apex-beat, often somewhat displaced outward.	Systolic thrill at the apex. Quite strong radial pulse.	Hypertrophy of the left, later of the right ventricle.	Loud systolic murmur at the apex. Pulmonic second sound accentuated.
2. <i>Mitral stenosis.</i>	Area of cardiac impulse enlarged, epigastric pulsation.	Diastolic thrill at the apex. Small and often irregular pulse.	Hypertrophy of the right ventricle.	Diastolic or presystolic murmur at the apex. First sound sometimes loud. Pulmonic second sound accentuated, and sometimes double.
3. <i>Aortic insufficiency.</i>	Apex-beat very strong, displaced downward and to the left. Visible pulsation of the medium-sized and smaller arteries.	Very strong, heaving apex-beat. <i>Pulsus celer.</i>	Marked hypertrophy of the left ventricle.	Loud diastolic aortic murmur, especially over the upper part of the sternum. Sounds in the arteries (femoral and brachial sounds, etc.). Sometimes a double sound or double murmur in the femoral.
4. <i>Aortic stenosis.</i>	Apex-beat displaced to the left.	Heart's action not very strong. Pulse small, sometimes slow.	Hypertrophy of the left ventricle.	Loud systolic aortic murmur, transmitted to the right.

[Bramwell reports that of 131 cases with macroscopic valvular lesion, the tricuspid was implicated in 33.58 per cent.; in all but 12 per cent. of these the changes were recent. Hence he thinks that tricuspid endocarditis is generally recovered from, and this he attributes to the relatively small strain to which that valve is subjected. The obvious therapeutic deduction is the importance of rest in mitral endocarditis.]

#### GENERAL SEQUELÆ AND COMPLICATIONS OF VALVULAR DISEASE OF THE HEART.

After having discussed, in what precedes, the mechanism of the single forms of valvular disease, and the physical signs derived from it, we must now describe a number of symptoms and sequelæ which may be present to a greater or less degree in all forms of valvular disease. With them we must also mention certain peculiarities of the individual forms.

**1. Subjective Symptoms.**—Fully compensated heart disease may exist, at least for a long time, without any subjective symptoms. This is especially the case in aortic insufficiency, more rarely in mitral insufficiency. Stenosis of the mitral or of the aortic valves almost always causes subjective symptoms. These symptoms often do not exist so long as the patient keeps perfectly quiet physically and mentally, but they develop under appropriate circumstances.

The existing subjective symptoms in heart disease are by no means always referred, in the first place, to the heart itself. It sometimes happens that the patient comes to the physician complaining of various digestive disturbances, or in other cases of headache, vertigo, etc. The physical examination alone leads us to recognize the heart disease. As a rule, the patient's first and chief complaint is directed toward his difficulty in breathing. The shortness of breath, which increases on any physical exertion, comes on quite early in many cases. In the later stages it is almost always the most distressing symptom. It arises as a result of the overfilling of the pulmonary vessels with blood, and the consequent delay in the pulmonary circulation, and impairment of the transfer of gases in the lung. In the later stages the anatomical changes in the lung tend to increase the dyspnoea. Until lately it was usually assumed that the distended capillaries encroached upon the lumen of the alveoli, and thus diminished their capacity for air. Basch, however, claims that the alveoli become distended by the passive congestion in the pulmonary circulation, because the capillaries are stretched (swelling of the lungs). One element in the development of the dyspnoea is the "pulmonary rigidity." The diminished expansibility of the lungs thus occasioned offers the same hindrance to respiration as is seen in pulmonary emphysema. Further investigations are necessary in order to determine the clinical importance of these conditions.

The secondary bronchitis of heart disease is a very great factor in the dyspnoea. This bronchitis is a frequent result of the pulmonary stasis. Often the respiratory distress increases and decreases simultaneously with corresponding variations in the bronchitis. A purely mechanical cause of dyspnoea is the compression of the lower portion of the left lung by great cardiac hypertrophy. The highest grade of dyspnoea is reached when finally hydrothorax and pulmonary oedema are developed. From what has already been stated, it is easy to see why lesions of the mitral valve which directly impair the pulmonary circulation lead sooner to shortness of breath than do lesions of the aortic valves. Sometimes the dyspnoea in heart disease occurs in paroxysms (cardiac asthma). This is probably in most cases dependent upon a sudden cardiac failure, especially involving the left ventricle.

Palpitation is the first subjective symptom to be mentioned of those which are referred directly to the heart. It is not yet accurately determined under what circumstances the action of the heart is perceived by the patient himself. We sometimes see an uncommonly strong action of the heart, as in aortic insufficiency, which is not perceived at all subjectively. In other cases, where objectively the heart is not especially active, palpitation forms the patient's chief complaint. It usually first appears when the heart disease ceases to be fully compensated. It is increased or first excited by physical exertion or mental excitement. In many patients attacks of palpitation occur without any discoverable external cause, due apparently to nervous disturbance. They are sometimes associated with a striking acceleration of the pulse, the so-called tachycardia.

Pain in the cardiac region is only rarely present in heart disease. The patients more frequently complain of an indefinite feeling of pressure and oppression in the chest, but attacks of severe pain in the cardiac region do occur, especially in patients with aortic insufficiency—pain shooting into the shoulders and arms, the

so-called *angina pectoris*, *vide infra*. Pains in the epigastrium and abdomen, which sometimes form the chief annoyance of the patient, usually depend upon passive congestion of the liver (*vide infra*), or upon the tension of the abdominal walls from ascites, œdema, etc.

We must finally mention here the rheumatoid pains in the joints and muscles, from which many patients with heart disease suffer.

The greatest subjective distress occurs in the last stages of heart disease, when general dropsy develops. The patient's helplessness usually culminates. All motions of the body are difficult, the dyspnoea and oppression in the chest constantly increase, until death finally releases the patient from his mournful condition.

**2. Sequelæ in the Heart Itself.**—We have already discussed the most important sequelæ of valvular disease in the heart itself, its hypertrophies and dilata-tions. It remains for us to describe the influence of the cardiac disease on the frequency and regularity of the heart's action, and also to discuss some secondary diseases of the cardiac muscle and of the pericardium.

In every well-compensated heart disease the heart's action may for a long time be of approximately normal frequency and regularity. We often find a constant and moderate acceleration of the pulse, which is easily increased from temporary causes. Permanent slowing of the pulse is rare in valvular disease of the heart. It is most frequent in aortic stenosis, where it is in part of compensatory significance. Marked changes in the frequency of the pulse depend upon severe disturbances of the nervous apparatus in the heart. Hence they are, as a rule, associated with irregular action of the heart. The frequency of the pulse may then reach 120 or 140 a minute. Diminution of the frequency to 50 or 30 are much rarer. We may mention as an unusual but interesting symptom the sudden attacks of enormous acceleration of the pulse to 200 or more—tachycardia—which seem to be especially frequent in mitral disease. In the interval there is usually a quiet action of the heart and a complete compensation of the heart disease. The increase in the pulse comes on quite suddenly, and is frequently associated with subjective feelings of palpitation and distress. It may last for several hours and then disappear again, also quite suddenly. The precise cause of these attacks is unknown. We may probably regard it as a temporary paralysis of the inhibitory apparatus of the heart.

Arrhythmia of the heart is of still greater importance than anomalies of the pulse-frequency. It always points to a severe disturbance of the nervous apparatus of the heart. The general circulatory disturbance which follows every valvular disease must of course make itself felt in the heart itself, and the nerves and ganglia of the heart can not remain undisturbed by it. Hence we generally see marked variations in the frequency and rhythm of the heart's action along with the other signs of beginning disturbance of compensation; but daily clinical experience teaches us that there is not a perfect parallelism between the two symptoms. We find often enough in heart disease quite a considerable irregularity of the pulse without any of the other signs of marked disturbance of compensation, and, on the other hand, we see in many patients an almost perfect regularity of the pulse up to death. In mitral disease, especially in mitral stenosis, arrhythmia of the heart is much more frequent than in aortic disease.

We can not here discuss in detail the different forms and symptoms of cardiac irregularity. An inequality in the intensity of the single beats is very often associated with the irregularity: the irregular pulse is also an unequal pulse. The weaker heart-beats sometimes cause a pulse which is no longer perceptible in the radial artery, so that we can determine the true frequency of the heart-beat, not by counting the radial pulse, but only by auscultation of the heart. The occur-

rence of the so-called *pulsus bigeminus* is of interest (see Fig. 32). A second weaker contraction follows the first strong systole, even before the ventricular diastole has fully ended, and then comes a longer pause. We feel alternately a strong and quite weak pulse. The latter may be imperceptible, so that it can be made out only by the sphygmograph. In such cases, with co-existing tricuspid insufficiency, we sometimes find the number of the venous pulsations twice as great as the number of the radial pulsations, because the second weaker contraction

FIG. 32.—Pulsus bigeminus.

of the heart produces a visible venous pulse, but not an appreciable radial pulse. On the whole, the *pulsus bigeminus* is a bad sign, since it always points to a marked disturbance of the cardiac innervation; but it may also pass away again and give place to a regular action of the heart.

Chronic valvular disease of the heart is often combined with anatomical changes in the cardiac muscle, and sometimes in the pericardium.

Among the changes in the cardiac muscle, cloudy swelling, and especially fatty degeneration of the muscular fibers, are the most frequent. The fatty degeneration of the muscle occurs either in a diffuse form, or in little yellowish spots, which are plainly visible on the papillary muscles and trabeculae. The opinion has often been expressed that fatty degeneration of the muscles is the cause of the disturbance of compensation; that the cardiac muscle performs its increased work until fatty degeneration ensues and reduces its strength. This theory does not entirely correspond to the facts. We have often seen the greatest disturbance of compensation in valvular disease when section of the cardiac muscle showed no fatty degeneration; and, on the other hand, we have seen great fatty degeneration of the heart, as in pernicious anaemia, when there were no signs of cardiac weakness during life. Anatomically, with our present aids to research, we can hardly ever decide with certainty whether the cardiac muscle was still capable of performing its normal functions or not. The usual state of the case is probably this, that fatty degeneration of the cardiac muscle is a result of the disturbance of compensation, and especially of the deficient supply of arterial oxygenated blood to the muscle (see the chapter on anaemia).

A frequent affection of the cardiac muscle in valvular disease is the presence of cicatricial changes and so-called myocarditic nodules in the substance of the heart. Chronic endocarditis may directly invade the subjacent parts of the cardiac muscles and set up a chronic inflammation there, but the cardiac cicatrices usually have another origin. The connective-tissue thickening beneath the endocardium is the result of a simple atrophy of the superficial muscular fibers due to the increased internal pressure of the blood, as in mitral or aortic insufficiency. The connective-tissue nodules within the cardiac muscle, however, depend upon a deficiency in the local supply of arterial blood. Simple sclerotic thickening of the coronary arteries, or complete embolism, or thrombosis of a small branch of one of them, is the evident cause of these circumscribed cicatrices. It is certain that the latter may reduce the capacity of the cardiac muscle for work, but, on the other hand, we often find cicatrices of myocarditis without any signs of a previous disturbance in the compensation of the heart. A fuller discussion of this subject will be found in the next chapter.

Pericarditis is not very rare as a result of chronic valvular disease. It is always a dangerous complication, and may cause death. Regarding its origin, we have found that almost all the cases of heart disease complicated with pericarditis show changes in the aortic valves. Hence it does not seem improbable to us that the origin of the secondary pericarditis in such cases is due to a direct

invasion of the pericardium by the excitants of inflammation passing from the aortic valves through the walls of the blood-vessel.

**3. Symptoms of Stasis in the Different Organs of the Body.**—As has frequently been mentioned in what precedes, the results of stasis of the blood make themselves manifest in heart disease in various organs. We have already spoken of the important results of blood stasis in the lungs. It remains for us to discuss the symptoms of stasis in the systemic veins.

As soon as the flow of venous blood into the right side of the heart is hindered, the venous stasis is shown by the cyanotic appearance of the patient. This cyanosis may exhibit any degree. In heart disease which is, on the whole, still well compensated, it is recognized only by the practiced eye of the physician as a slight bluish tinge of the lips, the alæ of the nose, the cheeks, or the nails. With the increase of the disturbance of compensation the cyanosis increases, if it be not modified by the co-existence of general anæmia. In mitral disease, especially in mitral stenosis, the cyanosis is usually more marked than in aortic disease. The large veins also become plainly visible as a result of their complete filling, especially the large external jugulars.

A further important symptom which follows the venous stasis is the œdema, the dropsy of heart disease. As we know from general pathology, every venous stasis, if it reaches a certain grade, leads to a transudation of the fluid of the blood from the capillaries. If the lymphatics can no longer carry this transudation away, it collects in the meshes of the tissues and leads to œdema. The œdema of heart disease, therefore, does not appear until the venous stasis has reached a certain degree, and the compensation of the heart disease has become impaired. It first appears in those parts where there is a particularly loose tissue, as in the eyelids and the scrotum, or where mechanical conditions favor its development. The legs usually swell first, especially about the ankles, because here the stasis of the venous blood is increased by gravity. At first, slight œdema appears only temporarily and by day, and disappears again while the body is in bed at night; but, as the disturbance of compensation increases, the œdema also constantly grows worse, especially in the dependent parts of the body, until finally it may reach the highest degree of dropsy. Besides the œdema of the skin, transudations into the internal cavities occur, especially into the abdomen and the pleural cavity.

The patient's distress is decidedly increased by marked œdema, as has already been said. All the motions of the swollen extremities are considerably impeded. Hydrothorax and ascites increase the dyspnoea, the former by compression of the lungs, the latter by upward pressure on the diaphragm. The passage of urine may be rendered very difficult by œdema of the prepuce. Besides that, we must mention that the skin, when very œdematous, is quite apt to become the seat of furuncular and erysipelatous inflammations.

The results of stasis in the internal organs may be best seen in the liver, spleen, and kidneys.

Passive congestion of the liver is manifested by quite a considerable increase in the size of the organ. The lower boundary of the liver dullness extends several fingers' breadth beyond the edge of the ribs, and the lower border of the liver may often be plainly felt. The liver may also be enlarged in cases where there are no other marked signs of passive congestion, such as dropsy. Quite severe pain in the hepatic region sometimes arises from the tension of the capsule of the liver. In the later stages the liver may grow smaller again from the partial atrophy of its cells.

Jaundice often develops in heart disease, as a result of passive congestion of the liver, or perhaps sometimes from a secondary duodenal catarrh. The peculiar mixture of a cyanotic and slightly jaundiced hue of the skin is very characteristic

in many cases, especially in mitral disease. It should be added that the yellowish discoloration of the skin in heart disease is probably not always a genuine icterus, but may be occasioned by the deposit of other pigments in the skin.

Passive congestion of the spleen arises if the stasis of the blood extends to the splenic vein. The spleen increases in size and becomes firm and dense. It is often hard to make out the congestion from the increase of the splenic dullness, because percussion of the spleen is uncertain if there be also ascites, hydrothorax, etc. We can often, however, plainly feel the enlarged spleen under the edge of the ribs on the left.

We recognize passive congestion of the kidneys by the changes in the urine. The amount diminishes; the urine becomes darker, more concentrated, of a higher specific gravity, and of greater acidity. A sediment of uric acid or of sodic urate very commonly forms in it. In marked degrees of stasis there is albumen in the urine. The amount of albumen is usually slight, but it may equal one third or one fourth of its volume. Under the microscope we find, in the urine of simple passive congestion, only an occasional hyaline cast, and a few red and white blood-corpuscles. Genuine acute or chronic nephritis, however, may also develop as a complication in heart disease.

We may refer the numerous gastric and digestive disturbances, like loss of appetite, vomiting, constipation, and diarrhoea, from which such patients often suffer, to the stasis in the blood-vessels of the stomach and intestines.

**4. Embolic Processes.**—The slowing of the circulation, and the disturbances in the nutrition of the walls of the vessels, which result from it, often give rise in heart disease to the formation of thrombi. These are situated in the heart itself, on the diseased valves, in the recesses between the trabeculae, in the auricles, etc., or else they form in the veins, especially in those of the lower extremity. From these thrombi fibrinous plugs may easily be set loose and enter the circulation, and thus give rise to embolic processes in distant organs. Some of the embolisms, whose clinical relations are especially important, have been more fully described elsewhere, and will be mentioned only briefly here.

Embolism of the pulmonary arteries, proceeding from venous thrombi or from thrombi in the right side of the heart, gives rise to hæmorrhagic infarction of the lungs. Its pathogenesis and symptoms have already been discussed in a previous section (see page 247).

Embolism of the cerebral arteries is a common cause of apoplectic attacks, which are not infrequent in heart disease, and which usually lead to hemiplegia. The anatomical cause of the hemiplegia in these cases is the embolic softening of the brain which develops. The details of this are given in the section on cerebral diseases (see page 737).

Embolism of the larger arteries of the extremities, like the femoral and the brachial, is much rarer than the forms mentioned. It leads to embolic gangrene of the extremities, unless an adequate collateral circulation can be established. The skin of the peripheral parts, the fingers or toes, first becomes cool, bluish, and at last, if the circulation be wholly checked, almost black. The gangrene advances slowly, usually occupying weeks. Ulcerations develop as the necrotic portions are thrown off. The affection is extremely painful. The patient soon becomes very miserable from the pain and the septic fever that usually attend the ulcerations, and extensive gangrene almost always ends fatally.

Embolism of the renal artery, with the formation of an ensuing hæmorrhagic infarction, may run its course without symptoms, but sometimes it may be recognized by the sudden appearance of blood in the urine.

Embolism of the spleen is often marked by swelling of the spleen and by severe perisplenitic pains. In other cases it is wholly without symptoms.

Embolism of a mesenteric artery is a very rare event. Its symptoms consist in a sudden intestinal hæmorrhage, in severe colicky pains, general collapse, and peritonitis.

**5. Complications on the Part of the Nervous System.**—The most important complication on the part of the nervous system—embolic softening of the brain—has already been mentioned. We must also state that cerebral hæmorrhage may occur in heart disease. It is especially frequent in aortic insufficiency, either as a result of co-existing atheroma of the cerebral arteries, or perhaps of the abnormally high tension of the walls of the vessels during systole.

Mental disorders have been repeatedly observed in chronic valvular disease. They are the result of the disturbance of the circulation, and the consequent impairment of nutrition in the brain. Hence they usually make their first appearance in the last stages of heart disease, at the same time with the other disturbances of compensation. The psychoses in heart disease most frequently have the character of melancholia, but conditions of excitement also occur.

**6. Secondary Affections of the Joints** are not rare in heart disease. As acute endocarditis develops in the course of acute articular rheumatism, so, on the other hand, rheumatic pains in the muscles and joints, and even acute swelling of the joints, associated with fever, appear in the course of chronic heart disease. Both affections—that of the heart and that of the joints—arise from the same specific cause of disease, and hence they may occur in varying succession.

**7. General Symptoms—Fever.**—In congenital heart disease, as we have said, the child's general nutrition is very backward. In heart disease in adults, however, we by no means always see an injurious influence on the general condition of nutrition. In many patients we even find a remarkably good development of fat. A marked general disturbance of nutrition, such as great anæmia and general emaciation, often develops in the later stages, especially in aortic insufficiency. The wasting is of course often hidden by the œdema.

In general, chronic heart disease runs its course without fever, but periods often occur in the course of the disease when there is a moderate and usually irregular fever. Marked disturbances of the general condition may or may not be associated with it. The basis of the fever is probably an acute exacerbation of the endocarditis, except, of course, in accidental complications. All variations occur, from a mild febrile movement without further symptoms to a severe acute recurring endocarditis (*q. v.*). In other cases the fever is connected with secondary swelling of the joints, or with embolic processes.

#### GENERAL COURSE AND PROGNOSIS OF VALVULAR DISEASE OF THE HEART.

The course of valvular disease of the heart is in most cases very chronic. It may last for years. So long as there is a complete compensation, the patient feels almost perfectly well; sometimes he even has no misgivings as to his trouble. The slight difficulty in respiration and the incapacity for physical exertion are noticed, but little attention is paid to them, because the patient is used to them. In other cases there is a moderate disturbance for a long time, but it may be borne quite easily if the patient is rational and prudent in his conduct.

We can not make any general statement as to the length of the stage of compensation, because cases differ very greatly in this respect. It depends in part upon the intensity of the heart disease, in part upon the external conditions under which the patient lives, and in part, certainly, upon the different individual capacity for work and power of resistance of the heart. Thus it happens that many cases last for decades, while in others severe sequelæ appear within a few months. External injurious agencies, acting on the patient, are of great

influence on the course of heart disease. Severe physical exertion, an injudicious manner of living, intercurrent febrile disease, mental disturbances, care, and anxiety are often followed by unhappy consequences.

If the first signs of disturbed compensation appear, if severe dyspnoea, slight oedema of the ankles, etc., develop for the first time, these symptoms may disappear again completely under proper treatment. Severe disturbances of compensation even, great general dropsy, associated with very weak and irregular action of the heart, may abate, after a few weeks' duration, and the patient may feel quite well again. Exacerbations of the disease may come on several times and as often improve. Finally, of course, the improvement is incomplete. Persistent oedema and the other results of venous stasis ensue, the symptoms constantly increase in severity, especially the dyspnoea, until the patient dies after a long and distressing illness. Immediately before death in heart disease, certain irregularities in the innervation of the heart and in the respiration sometimes develop. Among these the so-called Cheyne-Stokes phenomenon deserves especial mention. It consists in a peculiar periodical variation in the respiratory movements. There will be, first, a complete pause in the respiration (apnoea), and this will be succeeded by feeble breathing gradually becoming stronger, then gradually abating, and finally ending in another complete cessation of the respiration. The patient usually becomes more comatose during the cessation of respiration; his pupils contract. During the hard breathing the patient recovers somewhat, and his pupils dilate again. The chief cause of this rhythmical breathing is probably to be sought in the decided lowering of the excitability of the respiratory centre. During the apnoea a considerable amount of carbonic acid collects in the blood before the respiratory centre is sufficiently stimulated to resume its activity.

In regard to the single forms of valvular disease, aortic insufficiency generally gives the best prognosis, inasmuch as it may be very perfectly compensated for many years, but if severe disturbance of compensation once occurs in this form of heart disease, it gives a very unfavorable prognosis, since, as a rule, we can not re-invigorate the heart. Mitral insufficiency is also quite a favorable form of heart disease, which may be compensated for a long time. Mitral stenosis is decidedly more unfavorable in its prognosis, and is associated with more disturbance; but in all mitral diseases very severe conditions may improve once or even repeatedly. Aortic stenosis is also capable of quite good compensation, and in this respect it is even more favorable for the patient than mitral stenosis, but it often causes persistent cerebral symptoms, such as headache and vertigo, depending on anæmia of the brain.

Whether established valvular disease of the heart is curable is a question which can not be answered unconditionally in the negative. Of course in the great majority of cases it is in itself incurable; only its sequelæ can be prevented or removed to a certain degree. In children and young people, however, cases sometimes do occur, as we ourselves have seen, in which there are all the signs of a pronounced heart disease, but after a long time recovery is complete. Of course it is very hard to decide whether we really have to do with a valvular disease that has been cured, because simple dilatation of the heart, relative insufficiency of the valves, anæmic cardiac murmurs, etc., may easily be confounded with pure valvular disease of the heart.

Among the dangerous intercurrent accidents in valvular disease we must make especial mention of embolic processes, which may occur suddenly and without warning. The different forms of embolism have been mentioned above, and also the occurrence of cerebral hæmorrhage in heart disease. Intercurrent acute diseases, like typhoid and pneumonia, often take a very severe and dangerous course

in patients with heart disease, because they make increased demands upon the heart's capacity for work.

#### TREATMENT OF VALVULAR HEART DISEASE.\*

1. *Prophylaxis*.—Our remedies to prevent the development of heart disease are very limited. To avert endocarditis in articular rheumatism by the present method of treating acute rheumatism with salicylic acid is impossible. The probability of the onset of endocarditis may be lessened only so far as the whole duration of the disease is often considerably shortened by salicylic acid.

We can also do little in the way of prophylaxis against the development of heart disease that is chronic from the start, since the cause of the disease is in many cases wholly unknown to us. Those injurious influences deserve the most attention which may favor the development of arterial atheroma and its consequent chronic valvular disease. Undue indulgence in alcohol, too much smoking, and injudicious and luxurious ways of living, are especially to be avoided. The part which these factors play, however, in the development of a pure valvular disease, is certainly much less than their influence upon the development of certain functional and nervous disturbances of the heart (see a later chapter).

[There is evidence that the alkaline treatment of acute rheumatism lessens the danger of cardiac complications (see page 909).]

2. *Treatment of Compensated Heart Disease*.—If we have to treat a heart disease which already exists, but which is at the same time fully compensated, our treatment must be chiefly hygienic. The patient must be made aware of his heart disease without making him needlessly anxious. He must be told that his further good health depends in great part upon his own conduct, his discretion, and his perseverance. The patient must avoid everything which makes great demands upon the heart, or which may have a directly injurious influence on it. All violent bodily exertion, too intense mental work, and also all excesses in eating, drinking, smoking, etc., must be avoided. That the physician's directions will often collide with the demands of the patient's occupation, as well as with his favorite amusements and his habits, should not deter the physician from demanding the fulfillment of his prescriptions, at least so far as possible.

Treatment by drugs is usually unnecessary in compensated heart disease. We do not know a remedy which has a directly favorable action on heart disease. The protracted use of iodide of potassium, Fowler's solution, arsenite of antimony ("granules of antimony"), nitrate of silver, etc., has been recommended. The efficacy of these remedies is not proven. We can always try them, if a mild disturbance makes a prescription desirable and other remedies are not especially indicated. Beyond this, the physician is usually contented with an endeavor to improve the appetite and nutrition of the patient by means of iron, quinine, and bitters. If there is a suspicion that the heart disease may be due to syphilis, a trial of iodide of potash may be made, but a brilliant result from the employment of anti-syphilitic measures is hardly to be expected.

The employment of baths in heart disease deserves special consideration. Numerous experiences go to prove that they are not only well borne by cardiac patients, but that they exercise a peculiarly beneficial and invigorating influence upon the action of the heart. In this regard, the greatest reputation is possessed by the warm mud baths, which are rich in carbonic dioxide, particularly those at Nauheim. Even where there is incipient failure of compensation, there will be

\* A brief critical sketch of the mechanical treatment of circulatory disturbances, the so-called Cœrtel method, will be found in the appendix to the fifth chapter of this section.

marked improvement upon the use of these or similar baths. Patients may also employ at home either simple, or, still better, salt baths, at a temperature of 90·5°-93° (26°-27° R.). That a change of climate may prove beneficial is self-evident. It is particularly appropriate that patients with a tendency to bronchitis or rheumatism should spend the winter South.

3. *Treatment of Disturbances of Compensation.*—As soon as the compensatory activity of the heart begins to be impaired in valvular disease, as soon as dyspnoea and oedema ensue, we must, almost always, resort to digitalis. Digitalis in small doses has the property of reducing the frequency of the pulse, and also of strengthening the individual heart-beats, and thus increasing the blood-pressure. Digitalis is indicated in every case of heart disease if disturbances of compensation appear, and if the pulse also is abnormally small, of abnormally low tension, of increased frequency, and irregular. The desired action of digitalis, then, is to make the pulse slower, more regular, and of higher tension. Under the influence of an increase of the arterial pressure thus produced, the disturbances of compensation disappear in a way that is often surprising; the urine especially becomes more abundant, the scanty, dark, concentrated urine of passive congestion disappears, the daily amount increases, and the urine therefore becomes clear and of a low specific gravity. The oedema also disappears, the dyspnoea ceases, the head is clear, the general condition is better—in short, a complete compensation of the heart disease may be re-established. This change is sometimes accomplished in a comparatively short time—in a few days or weeks.

The dose in which digitalis is to be prescribed can not be given absolutely, because the amount of the active principle which the plant contains does not seem to be quite alike in different places. This is the explanation of the somewhat different statements as to the dose to be employed. In general, we should begin with small doses. We usually prescribe an infusion of the leaves of a strength of 1 or 1·5 parts of digitalis to 150 parts of distilled water—a teaspoonful every one or two hours. The addition of syrup causes the medicine to decompose more easily, and is quite useless. The favorite addition of diuretics, liquor potassii acetatis, 30 parts, or boro-tartrate of potassium and sodium, four to eight parts added to the infusion, diminishes the strength of the remedy. It is advisable to give digitalis in powder, because we can thus define the dose more accurately. We prescribe powders of one or two grains of digitalis leaves (grm. 0·05-0·1) with seven or eight grains of sugar (grm. 0·4), and give that amount every two or three hours. The drug may also be given in capsules or suspended in water. It is often a good plan to inclose the powder in capsules. The other preparations of digitalis, the vinegar and the tincture, are less active. We usually prescribe the latter when a patient with a moderately persistent disturbance of compensation is to use digitalis in small doses for a long time. We have not yet succeeded in isolating the active principle of digitalis in a durable form. The "digitaline" preparations brought into the market up to the present time are uncertain in their action, and hence are properly but little prescribed.

Digitalis is a remedy which is not free from danger, because there is a stage in its action, which often appears, when it is injurious. The pulse then sinks below the normal, becomes weaker and also irregular and intermittent, if it was previously regular. The patient's general condition becomes bad, nausea and vomiting set in, and a state resembling collapse may arise. Therefore it is a very important rule, never to prescribe digitalis in large doses unless the patient can be observed constantly and carefully. As soon as the first signs of the unfavorable action of digitalis occur, the remedy must be at once omitted. Then we give some strong wine, or strong *café noir*, to prevent the patient's further collapse. Since digitalis is one of the remedies which have a so-called cumulative action, the occurrence

of symptoms of poisoning may be quite rapid and unexpected. We do well, therefore, if the desired favorable action follows the exhibition of digitalis, if the pulse has become quieter and more regular, and diuresis has been established, to omit the digitalis. We usually let the patient take the remedy for two to four days, and then omit it. The action of the digitalis continues for several days afterward. Sometimes, however, nausea and vomiting are occasioned by the ingestion of no more than fifteen to twenty grains (grm. 1 to 1.5) of digitalis. The drug must then be stopped, although a decided beneficial effect may be observed even on the day after the nausea. After leaving off the digitalis we usually prescribe a diuretic, like acetate of potassium, squills, boro-tartrate of potassium and sodium, or diuretic herbs. If the pulse again becomes rapid and irregular, we at once resume the digitalis. In such cases, where the patient has used digitalis repeatedly, we must gradually increase the dose. The patient gets accustomed to the remedy, as happens with so many other drugs. There is no maximum dose, and in individual cases we must find out the requisite amount by trial. Many patients finally become genuine "digitalis eaters," and can not exist without large doses—seventy-five grains (grm. 5) or more of the powder a day. In very many cases, unfortunately, the favorable action of the digitalis finally ceases entirely with large doses. The remedy is then no longer "borne," and we must omit it entirely. By that time the last stage of the disease has also usually been reached.

If we have to treat a patient with symptoms of stasis, and the pulse seems neither especially small nor frequent, nor irregular, we may nevertheless try the effect of digitalis, but we must be very cautious in the size of our dose. The question is often hard to decide whether to give a patient with aortic insufficiency digitalis or not. In this form of heart disease there is often a very strong and regular, though of course abnormally frequent pulse, in spite of the most pronounced disturbance of compensation. With this we must not forget that, in spite of the high pulse, the mean pressure in the arteries is low, and hence in most patients with aortic insufficiency we can very well make a trial with digitalis. This is often crowned with success; but still the drug seems to be less often efficient in aortic than in mitral disease.

In some, but fortunately not many, cases, the digitalis is ill-borne from the start, because it excites severe nausea and vomiting. In general the incidental action of digitalis on the stomach is one of its troublesome properties. If the digitalis is not borne in one form, we try another. We give the powder instead of the infusion, or *vice versa*, or we employ the tincture. In such cases we sometimes succeed if we give the digitalis as an enema, using a one-per-cent. infusion.

Caffeine deserves the first mention among the substances having a similar action, which have of late been recommended as substitutes for digitalis by Lépine, Riegel, and others. Given in repeated small doses, a total of fifteen to twenty grains a day (grm. 1.0 to 1.5), it often slows, regulates, and strengthens the activity of the heart, and also increases the arterial pressure. The salicylate of caffeine and sodium is chiefly used, three to five grains (grm. 0.2 to 0.3) of the powder, and also the benzo-citrate of caffeine in the same or smaller doses. The latter is also given subcutaneously. Besides caffeine, we may also mention here *adonis vernalis* and *convallaria majalis*; but none of these drugs are as reliable as digitalis. In conditions of cardiac weakness, tincture of *strophanthus* (ten drops several times a day) is sometimes decidedly beneficial.

Digitalis is used more commonly in this country in the form of the tincture. The urine affords a good guide as to the safety of the continuance of the drug; as long as the renal secretion is sufficient in quantity, and increasing rather than diminishing, there is no danger of the toxic effects. It is, consequently, a good plan

to follow carefully the twenty-four-hour quantity of urine when this can be done.

There are cases in which digitalis must be taken for long periods, but it should then be given only twice a day, with twelve hours' interval between the doses, unless the patient has ready access to his physician; there is then less risk of toxic symptoms. To the list of drugs the action of which is similar to that of digitalis and which may be substituted for it, if it disagrees or is without effect, may be added helleborein and spartein sulphate (gr. j-ij). Fraser reports well of strophanthin; but a more extended use is desirable.

In mitral cases, with or without secondary tricuspid regurgitation, where the cyanosis and other symptoms show that the right heart is engorged with blood which it can not propel onward, the relief afforded by venesection, or by a dozen leeches in the hepatic region, may be very great. Until the veins are relieved either in this way or by free purgation, digitalis and stimulants are useless, and a resort to them results merely in a loss of time, and perhaps in a loss of life which might be saved.]

4. *Symptomatic Treatment.*—Some symptoms which often occur in heart disease demand a special description.

Dropsy is a symptom of venous stasis, and disappears if compensation be restored, spontaneously or by the use of digitalis. Complete rest in bed and elevation of the swollen parts serve as the chief aid in removing the dropsy. Dropsical patients ought also to change their position in bed frequently, if possible, that there may not be too much œdema collected in the dependent portions of the body. It is a good plan to wrap up the swollen arms and legs with flannel bandages under gentle pressure. Mild massage of the œdematous parts may sometimes be of advantage. The amount of liquid ingested is to be limited, if possible. Of internal remedies, besides digitalis and similar drugs, the true diuretics, such as acetate of potash, are to be considered. They are sometimes ordered in combination with digitalis and sometimes alone, particularly when digitalis can not be borne or is not indicated. Calomel is sometimes especially efficient in cardiac dropsy. Its diuretic influence has lately been emphasized by Jendrassik and others. It is prescribed in powders of three grains (0.2 grm.) three to five times a day. Often a very marked diuresis will be caused after one or two days, with rapid abatement of the dropsy. The administration of the remedy is stopped as soon as the diuresis begins. It is also omitted, of course, if stomatitis develops.

In the last stages of heart disease the patient's condition may be particularly distressing from the severe general œdema. It is then justifiable to remove the ascites or hydrothorax by puncture, and to let the œdema drain out by scarification of the skin—little pricks with the point of a knife—in order to procure relief for the patient. The scarification of the skin, however, is dangerous, and is not to be employed without urgent indications, because erysipelatous inflammation, etc., is apt to ensue at the point of incision. We can recommend little silver capillary trocars (the so-called Southey's trocars), to which a thin rubber tube is attached. By the aid of these trocars we can drain off large amounts of serum. We must always use great cleanliness, however, and the utmost disinfection of the skin, wrapping the parts in carbolyzed jute or salicylated cotton. In patients with heart disease it is not, as a rule, advisable to attack the dropsy by sweating, by hot packs, or pilocarpine.

The dyspnoea of heart disease is usually the most distressing symptom of all. Here, too, our chief task is of course to restore the compensation; but this failing, we must try to relieve the dyspnoea symptomatically. Morphine is most efficient in this respect. In general, morphine is, next to digitalis, the most indispensable remedy in the treatment of severe heart disease. It is usually well borne, and

procures great relief, especially if given subcutaneously. If we have to do with the last stage of the disease, we need not spare large doses. Otherwise, of course, caution is necessary. In practice we must often prescribe external applications to the chest, mustard-plasters, hot poultices, and also hot foot-baths with mustard, ashes, etc. In severe cases their action is slight. Acetate of lead in large doses sometimes seems to have a favorable influence in severe dyspnoea, especially with threatening pulmonary oedema. We give the powder, up to a grain and a half (grm. 0.1), every two or three hours, and it is often a good plan to add half a grain or a grain (grm. 0.03 to 0.05) of opium. We can also frequently obtain distinct relief for the patient by a vigorous drastic purge, with compound infusion of senna or gamboge. Inhalations of nitrite of amyl seldom have a beneficial effect.

Palpitation, constant or paroxysmal, is met by applying ice to the cardiac region; sometimes the "heart-flasks," made of tin, act very well. In patients with aortic insufficiency and very excited action of the heart, we may recommend the protracted use of ice. The narcotics are the most efficient internal remedies, especially morphine, which, of course, we should reserve for severe cases. If the palpitation is of a lesser degree, we may try bromide of potassium, or cherry-laurel water, eventually with equal parts of tincture of digitalis, twenty to thirty drops of the mixture two or three times a day.

The subcutaneous use of morphine is again by far the most potent remedy in the anginose attacks, associated with pain and a feeling of distress. We may also use cutaneous irritation, mustard-plasters, etc., ice, and perhaps strophanthus or nitrite of amyl.

We may prescribe bitter remedies—tinctura amara (P. G.), or compound tincture of cinchona—and muriatic acid for the loss of appetite, in case this is not improved by regulating the activity of the heart. Besides that, we must always endeavor to get a regular evacuation of the bowels.

For the attacks of faintness and vertigo, occurring especially in aortic stenosis, as a result of cerebral anæmia, we may prescribe a horizontal position, and stimulants—wine, ether, and Hoffmann's anodyne. If the cerebral symptoms depend upon venous stasis, we try to remove it by ice, mustard plasters to the neck, and thorough derivation to the intestines.

Especial accidents and complications, like pulmonary oedema, infarctions, or apoplexy, are to be treated according to the usual rules.

## CHAPTER III.

### MYOCARDITIS.

*(Indurated Degeneration, Myodegeneration of the Heart. Infarction of the Heart. Sclerosis of the Coronary Arteries.)*

**Ætiology and Pathological Anatomy.**—We have of late learned about a number of affections of the heart in which all the results of disturbance of the circulation may finally appear, without any evidence of anatomical disease of the valves, either during the patient's life or at the autopsy. We have to do here with a lesion of the cardiac muscle itself, or of its nervous apparatus, which reduces the functional capacity of the heart, and thus excites precisely the same disturbances of the circulation as are produced in valvular disease of the heart by purely mechanical conditions.

In a number of cases—but by no means in all, as we shall see in the next chap-

ter—we succeed in detecting striking anatomical changes in the cardiac muscle. The heart is on the whole enlarged, chiefly dilated, though its walls are usually somewhat hypertrophied (*vide infra*). In pure, uncomplicated cases the valves prove entirely normal. If, however, we examine the cardiac muscle closely, we find it studded with whitish, lustrous, indurated spots, arranged irregularly and often very abundant. They consist microscopically of cicatricial connective tissue, while the muscular fibers have wholly or in large part been destroyed. The seat of this induration is chiefly in the left ventricle, especially at the apex and in the anterior wall, but we may also find indurations in other portions of the heart. We often see them appearing through the endocardial or pericardial surface of the heart as dull, slightly sunken places. The papillary muscles may also undergo marked cicatricial degeneration.

The changes in the heart just depicted were formerly considered to be of an inflammatory nature, and hence were given the name of myocarditis; but their development is connected, in the great majority of cases, as Weigert, Ziegler, Huber, and others have shown, with changes in the coronary arteries and their branches. In most of the uncomplicated cases of so-called myocarditis we find marked atheromatous changes in the coronary arteries, usually coincident with a more or less extensive, general arterio-sclerosis (*vide infra*). These changes may lead in circumscribed places to a complete closure of a branch of the coronary artery by thrombosis, and thus give rise to the formation of a true infarction of the heart by cutting off the further blood-supply. These infarctions show, in fresh cases, a decided brownish-yellow, hæmorrhagic color. The finer histological changes consist in a loss of their nuclei by the muscular fibers, and their degeneration into a crumbling, cheesy detritus. By the new formation of connective tissue the peculiar cardiac indurations finally arise, which are therefore to be regarded as true infarction cicatrices.

In many cases of indurated degeneration we can not discover any complete closure of the branches of the coronary artery by thrombosis. Here we have to do only with changes in the caliber of the vessel by the arterio-sclerotic process, and a consequent diminution of the arterial blood-supply of the cardiac muscle. In all places where this diminution of the blood-supply becomes extreme, we also find a gradual deterioration of the muscular fibers, and their replacement by connective tissue. Where the arterial blood-supply is adequate, either directly or from the collateral circulation, the muscles remain intact. This is the reason why we often find sclerosis of the coronary arteries unaccompanied by indurated myocarditis.

Besides the cases of uncomplicated myocarditis just described, we often see the same cicatricial changes in the cardiac muscle combined with valvular affections. The cardiac indurations, then, are either due to a co-existing sclerosis of the coronary arteries, or they stand in a closer relation to the endocardial process. The endocarditis may invade the cardiac muscle immediately. This method of origin of the myocarditis may be easily recognized by the localization and extent of the diseased parts. In other cases the endocarditis may give rise to embolic processes in the cardiac muscle. Thus the embolic infarctions of the heart arise in just the same way as do the thrombotic infarctions above described.

It remains for us to describe a number of sequelæ and combinations of indurated myocarditis. As a result of the extensive cicatricial formation, it may happen that a circumscribed portion of the wall of the heart, usually of the left ventricle, becomes thin and yields to the blood-pressure acting upon it from within. Thus arises a partial protrusion of the wall of the heart, a so-called cardiac aneurism. Such an aneurism, and also an extensive, fresh infarction in the heart, may in very rare cases lead to a rupture of the heart, with effusion of blood into the

pericardium and sudden death. A more common occurrence is that sometimes in places where the cardiac cicatrices reach the endocardium, parietal thromboses form in the heart, and give rise to embolic processes in distant organs.

Dilatation of single portions of the heart, especially of the ventricles, depends upon a general yielding of the walls of the heart. If at the same time there is a hypertrophy of the cardiac muscle, we must look for special causes for it. Hypertrophy of the left ventricle usually depends upon co-existing general arterio-sclerosis, upon co-existing contracted kidneys, and the like. Again, it is probably often the case that the same causes give rise simultaneously to the atheroma and to the hypertrophy of the left ventricle (see the following chapter). Hypertrophy of the right ventricle may have its origin in co-existing chronic pulmonary affections, like emphysema. In some cases the hypertrophy of the right ventricle is due to the inadequate action of the left ventricle. If the left ventricle begins to grow weak, the stasis backward from it must extend through the pulmonary vessels into the right side of the heart. In consequence of the increased demands upon the right ventricle this becomes hypertrophied. In cases of indurated myocarditis combined with valvular disease, the hypertrophy of single portions of the heart depends, of course, in part upon the valvular disease.

Regarding the special ætiological factors which lead to sclerosis of the coronary arteries, and thus to indurated myocarditis, they are in many cases as little known as the causes of arterio-sclerosis in general (*vide infra*). Chronic alcoholism and luxurious habits of life are very often the predisposing causes which are to be put in the first rank. Perhaps constitutional syphilis plays a not unimportant part, since it may lead to changes in the coronary arteries, as it has long been known to do in the cerebral vessels. Constant mental excitement is also regarded as a factor; but this must be regarded as much more a cause of the conditions to be described in a following chapter. Heredity, however, is of greater influence, as it seems to play a certain part in the development of arterio-sclerosis. Finally, we must remember that the atheromatous process occurs much more frequently in advanced life than in young people; hence indurated myocarditis is a disease chiefly to be observed in the aged. Men are more frequently attacked by it than women.

Although we have so far spoken exclusively of chronic indurated degeneration of the cardiac muscle, which, as we have said, is not of a peculiarly inflammatory nature, we must also add that there is a true purulent inflammation of the cardiac muscle. This is one of the symptoms of a general, infectious, and especially a pyæmic process, or of malignant acute endocarditis, so that we may refer to the description of these diseases in regard to abscess of the heart.

**Clinical History.**—We must first mention that sometimes quite extensive cicatricial formation may be found in the cardiac muscle *post-mortem*, without the occurrence of any manifest symptoms referable to the heart during life. We see, then, that the heart may, under some circumstances, undergo quite a considerable loss in its contractile substance without injury.

In many cases, however, the heart's capacity for work suffers so much that the same symptoms arise as in valvular disease. The course of such cases may be very chronic. The symptoms begin quite gradually. The patient first has a slight dyspnoea or palpitation, and a feeling of distress in the chest, but only from external causes, like slight physical exertion. He sometimes suffers from a striking general weakness. He gets tired easily and feels heavy, and more or less incapable of any mental activity. The symptoms gradually increase, and just the same results of disturbance of the circulation appear as in all the other forms of heart disease. The difficulty in breathing becomes more marked, œdema occurs,

signs of stasis in the liver, intestines, and kidneys appear—in short, the well-known type of every uncompensated heart disease develops.

Physical examination of the heart shows marked anomalies of the heart's action in all severe cases. The pulse is often irregular in regard to its rhythm and the intensity of its single beats, but the arrhythmia may also be wholly absent in spite of the degeneration of the myocardium, as we have often convinced ourselves. The pulse is at first quite strong and full, later it becomes weaker, of lower tension, and at last sometimes very small and scarcely perceptible. It may be increased in frequency, but we quite often notice in chronic myocarditis, especially in the early stages, a persistent slowing of the pulse to 60, 50, or even less, in a minute. With this slowness of the pulse there is also frequently irregularity of the heart's action, especially the appearance of occasional double beats (*pulsus bigeminus*). Percussion usually shows an increase of the heart's dullness, due to dilatation or hypertrophy of the heart, the increase being either general or chiefly on one side. Auscultation shows the absence of any murmur, and hence the absence of valvular disease. The heart-sounds are distinctly audible, and sometimes quite loud and valvular, but in the later stages often low and obscure. The pulmonic second sound is accentuated, when there is stasis of the pulmonary circulation. In several cases we found the second sound for a long time very plainly divided—reduplicated. We must also mention that sometimes in pure myocarditis a systolic murmur is heard at the apex which is due either to a relative insufficiency of the mitral valve, or to its incomplete closure, as a result of defective muscular action of the left ventricle.

The whole course of chronic myocarditis is in most of its relations precisely analogous to that of chronic valvular disease, so that we need not describe its peculiarities in detail. The patient is alternately better and worse. Severe symptoms of general stasis and manifest weakness of the heart may appear, and, under favorable circumstances, may disappear again. The picture of the disease may be complicated by embolic processes in the brain, the lungs, etc., which usually arise from thrombi in the heart (*vide supra*). Finally, perhaps after the disease has lasted for years, the patient dies from general dropsy or from some intercurrent disease.

We must mention one symptom which has often been brought into special relation with sclerosis of the coronary arteries and with chronic myocarditis. We mean the attacks of so-called angina pectoris, the stenocardiac paroxysms. These attacks consist in a sudden, intense pain in the cardiac region, which shoots into the back, the left shoulder, and the left arm. This pain is associated with a marked feeling of constraint and distress. There is no particular dyspnoea in pure angina pectoris. The attacks last from a few minutes to half an hour, and may be interrupted by entirely free intervals.

We can not deny that such attacks occur in indurated myocarditis, due to sclerosis of the coronary arteries, but, on the other hand, many cases run their course without angina pectoris, and angina pectoris may also occur both in other forms of heart disease and as a pure neurosis. Hence we must not overestimate the significance of angina pectoris in the diagnosis of sclerosis of the coronary arteries. Besides angina pectoris, attacks of dyspnoea (cardiac asthma) and of faintness also occur in chronic myocarditis, the faintness being especially frequent in cases associated with a slow pulse. The dyspnoea is usually due to a sudden weakness of the left ventricle, while the origin of the faintness is not yet fully explained (cerebral anæmia?).

It is a very important clinical fact that, in not very rare cases, indurated myocarditis is the sole apparent cause of sudden, apoplectic death. It usually happens in elderly people in comfortable circumstances and good livers, who up

to that time have not regarded themselves as really ill; but they have repeatedly had slight attacks of vertigo, of oppression, etc. Suddenly a sort of apoplectic attack comes on, often after some definite cause, after dinner, or after some physical exertion or mental excitement. Death follows in a few moments, or after a deep coma that lasts for several hours or even days. The diagnosis often remains in doubt in such cases, especially if we have not known the patient previously. The autopsy shows, as the sole pathological lesion, a sclerosis of the coronary arteries, with a more or less extensive cicatricial formation in the heart. Apparently in these cases the moment must suddenly arise when the supply of blood to the heart is insufficient, and thus death is caused. Experiments upon artificial closure of the coronary arteries, by Cohnheim and others, agree perfectly with the clinical facts above mentioned. Artificial narrowing of the coronary arteries may also be well borne for a long time, until suddenly both halves of the heart stand still in a condition of diastole. In rare cases sudden death may also be due to embolism of the main trunk of the coronary artery, or, as we ourselves have seen in one case, to the bursting of a focus of myocarditis with hæmorrhage into the pericardial cavity.

**Diagnosis.**—The diagnosis of chronic myocarditis is by no means always easy and certain. We must first determine that there is a cardiac lesion of some kind. This is usually easy to do from the secondary symptoms of stasis, the condition of the pulse, the heart's dullness, etc. Then the question arises whether we have to do with a valvular disease or with a myopathic disease of the heart. Here auscultation must chiefly decide. The absence of a heart murmur, in spite of other definite signs of heart disease, speaks against valvular disease, but not with complete certainty. All murmurs may be absent in the last stages, especially with a high degree of mitral stenosis, and hence we may easily confuse mitral stenosis with myocarditis, particularly when there is marked arrhythmia of the heart. On the other hand, we have already stated that, in pure myocarditis, with the valves intact, functional murmurs may be present, which may lead to an erroneous opinion as to valvular disease. If by long observation we have excluded a valvular disease, we still have left the distinction between myocarditis and pure idiopathic hypertrophy of the heart, or fatty heart (see the following chapters). We hold it impossible to make this distinction with certainty. The conditions of disease mentioned all furnish the same clinical picture of cardiac insufficiency, but during life we can only suspect what finer anatomical relations are the ones which cause this insufficiency, and we can never diagnosticate them with certainty. Irregularity of the pulse occurs both in indurated myocarditis and in pure hypertrophy and dilatation, without discoverable cicatricial nodules in the substance of the heart. A persistently slow pulse, attacks of angina pectoris or cardiac asthma, the evidence of co-existing sclerosis of the arteries of the body, such as the radial, temporal, or femoral, in connection with other symptoms, make the diagnosis of indurated myocarditis probable, but never completely certain. In cases, too, with a sudden apoplectic attack—"heart apoplexy"—it is often impossible to make a certain distinction between it and cerebral embolism, or cerebral hæmorrhage.

**Prognosis.**—The prognosis is as serious as in any valvular disease. Recovery is impossible, but even extensive cicatricial formation in the heart may probably last for years without causing much disturbance. We must always be prepared for the occurrence of disturbances of compensation, and the manifold sudden accidents to which patients with myocarditis are exposed, but we can not foretell the time of their occurrence.

**Treatment.**—The treatment of chronic myocarditis must be directed first to the dietetic and hygienic care of the patient. This is of the greatest importance.

For obese persons accustomed to high living, a moderate, simple diet must be accurately prescribed. Alcoholic beverages must be greatly limited or wholly forbidden, and not more than two or three cigars allowed per diem. Moderate bodily exercise is beneficial, and indeed necessary, for the promotion of the circulation and the more rapid diminution of the obesity, but the patient must be warned against too violent exertion, nor can great mental effort be permitted. In summer, a quiet life in the country or some mountain region is to be advised, or, under suitable circumstances, the cautious use of the waters of Carlsbad, Kissingen, Marienbad, or Nauheim. Frequent tepid baths or mud baths may usually be employed even at home with advantage. With disturbance of compensation, and with abnormally frequent, weak, and irregular action of the heart, digitalis and similar remedies are indicated, just as in valvular disease. In cases with an abnormally slow pulse, we may use them, provided great caution is exercised, but we must also be governed by the other prevailing symptoms. In attacks of angina pectoris the subcutaneous injection of morphine is by far the most efficient and often an indispensable remedy. We may also try nitrite of sodium, 1 or 2 parts to 120 of water, two or three teaspoonfuls daily. The inhalation of a few drops of nitrite of amyl is also sometimes beneficial, but more often it has no effect. In cardiac asthma, stimulants like strong black coffee, ether and camphor, and often narcotics, are indicated. Mustard-plasters, cold and warm poultices, hot foot-baths, etc., are also employed. Iodide of potassium and arsenic are especially recommended for continued use in myocarditis. The first remedy sometimes seems to be of service, and is especially to be recommended where there is a suspicion of former syphilis. With regard to all further details we must refer to the preceding chapter.

#### CHAPTER IV.

##### IDIOPATHIC HYPERTROPHY AND DILATATION OF THE HEART.

(Over-exertion of the Heart. Weakened Heart.)

**Ætiology and General Pathology.**—Besides the forms of heart disease already described, cases not infrequently occur which present all the signs of an uncompensated heart disease during life, and which show at the autopsy a hypertrophy of the heart or a dilatation of its cavities, but no other abnormality, either in the valves, in the coronary arteries, or in the cardiac muscle. The cardiac hypertrophy, which involves the left ventricle chiefly, but often both ventricles, can not be regarded as secondary in the ordinary sense of the word, for in the heart itself and in the other organs we find nothing which can call forth a secondary hypertrophy of the cardiac muscle—no valvular disease, no chronic nephritis, no general arterio-sclerosis, and no pulmonary emphysema. Hence we term these cases "primary idiopathic" cardiac hypertrophy, in the sense that we can not discover any other primary disease in them. Nevertheless, we must also look in such cases for factors which during life result in increased work for the heart, because only thus can we understand the development of this form of cardiac hypertrophy.

Such factors may in fact often be discovered. In a few rare cases a congenital narrowness of the aortic system plays a part, since by this the heart's work is manifestly increased. The observations upon this point, however, are very scanty, so that we can not yet estimate with certainty the practical significance of this arterial anomaly.

Excessive physical exertion is of much greater ætiological importance. We

not infrequently see idiopathic cardiac hypertrophy develop in the hard-working classes—in blacksmiths, locksmiths, pack-carriers, and vine-dressers ("Tübinger heart"). The increased work of the heart upon every physical exertion is here repeated almost every day in the year, and must finally lead to a marked degree of hypertrophy from labor. This is the chief form which has been termed "cardiac over-strain."

Numerous cases of idiopathic hypertrophy of the heart may often be regarded as the result of long-continued gourmandizing, hence the frequent appearance of hypertrophy in the obese, and particularly in great beer-drinkers. The constant excessive ingestion of liquid undoubtedly gives rise to an increase in the amount of blood, and so overburdens the heart. Likewise the abundant ingestion of food occasions a constant slight increase of the blood pressure, and so, again, an increase of the work demanded of the heart. These influences are finally reinforced by all the consequences of increasing obesity, in its relations to the circulation, which we shall consider more minutely in the chapter upon obesity. Excessive indulgence in beer has certainly the worst effect upon the heart. There is both a large amount of fluid, four and sometimes even eight or ten quarts a day, and a large amount of nourishment. Four quarts (litres) of beer contain about eight ounces (250 grm.) of hydrocarbons, in solution, and therefore capable of complete absorption into the circulation. This explains the great frequency of cardiac hypertrophy which Bollinger has shown to exist at Munich; but the "Munich beer-heart" is seen with unfortunate frequency in other towns than Munich. The alcohol is probably not a factor in the development of the hypertrophy of the heart, but we may well suppose that it promotes, or at least hastens, the degenerative changes in the cardiac muscle, and particularly in the cardiac nerves, which at last render the heart's action inadequate and the circulation imperfect.

Finally, however, there are always a number of cases in which none of the causes so far mentioned can be discovered. In these cases we are inclined to conjecture that there is an abnormal nervous irritation of the heart, which excites it to increased activity, and hence causes its hypertrophy. The cases which seem to be connected with continued mental excitement in business men, etc., probably belong to this group. We may also recall the cardiac hypertrophy in exophthalmic goitre (*vide infra*).

Since the exciting causes above mentioned to explain the origin of the so-called idiopathic cardiac hypertrophy do not by any means constantly result in this condition, we must also assume a special individual, and sometimes apparently a hereditary predisposition, a congenital or acquired weakness of the cardiac muscle. Up to a certain degree a healthy, strong heart can respond to the increased demands made upon its activity. We are even justified in considering a certain amount of hypertrophy in such cases as by no means pathological, just as there is nothing pathological in the hypertrophied muscles of a gymnast; but experience shows that the relations of the cardiac muscle are different from those of the muscles of the body, for the hypertrophied heart does not permanently fulfill the increased demands put upon it, but it gradually begins to be paralyzed, and becomes insufficient. Hence the English physicians, since Stokes's time, term the cases of cardiac insufficiency, without any apparent coarse anatomical lesions of the valves or muscle, "weakened heart." This term does very well for those cases where the symptoms of cardiac insufficiency have appeared before much hypertrophy has developed. There are pure cases of weakened heart in which the heart seems merely dilated and its walls flabby, and not at all or only slightly hypertrophied. Such a condition shows all the clinical symptoms of a chronic heart disease with disturbed compensation.

It may be mentioned here that dilatation of the heart may be very acute in

its development under certain circumstances, if great demands are temporarily made upon a heart which is not capable of very much exertion. Acute dilatation of the heart has been seen in soldiers after a few forced marches. We once saw a case in a previously healthy man who fell into the water and could only with difficulty be saved from drowning. Acute dilatation also occurs in the course of severe febrile diseases, like typhoid, intermittent, or pneumonia, which are sometimes associated with manifest weakness of the heart. In previously diseased hearts, too, acute dilatation may develop after some special cause. These acute dilatations may in many cases be restored to normal dimensions, but they always point to a certain degree of permanent weakness of the heart.

**Clinical History.**—Idiopathic dilatations and hypertrophies of the heart may certainly exist for a long time without causing the patient any subjective disturbance. The symptoms begin when the heart can no longer respond to the demands made upon it, and when it begins to be paralyzed. Then all the symptoms of cardiac insufficiency arise, in just the same way as in valvular disease and in the severe muscular diseases of the heart. Hence we need not go into the details of the disturbances of compensation again. The whole series of symptoms of stasis, as well as the attacks of angina pectoris and cardiac asthma, described in the preceding chapter, also occur in idiopathic hypertrophies and dilatations of the heart.

The general course of the disease differs considerably in individual cases. Sometimes there is moderate difficulty in breathing for a long time, especially on any physical exertion. The patient often complains of great languor, of nervous irritability, and sometimes of attacks of vertigo and faintness, and a tendency to perspiration. The appetite is poor, and there is very apt to be constipation. The condition may become quite suddenly worse after any marked injurious influence, especially after great physical exertion or mental excitement. The pulse is small, weak, and irregular, the heart-sounds grow feeble, the dyspnoea and oppression in the chest increase, the amount of urine diminishes, and œdema appears in the legs. We now have the complete picture of an uncompensated heart disease. With proper treatment the symptoms may disappear again; but, sooner or later, they return. Death finally ensues from general dropsy or from some complications or intercurrent attacks, among which we may mention embolic processes.

If the patient avoids all injurious influences by a discreet and prudent way of living, the course of the disease may be quite favorable for years. It is not improbable that a number of mild cases may be restored to health, or at least remain stationary.

**Diagnosis.**—The diagnosis is based on the presence of the ætiological factors, and on the same symptoms as generally point to a disturbance in the heart—namely, palpitation, shortness of breath, acceleration and arrhythmia of the pulse, etc. Physical examination in the later stages of the disease gives an increase of the heart's dullness in both directions, usually chiefly to the right. Auscultation permits us to exclude valvular disease by finding the heart-sounds everywhere distinct. We have left, then, only the hypothesis of an idiopathic hypertrophy of the heart or a chronic myocarditis. As we have already said, we consider it impossible to make a clinical distinction between these two diseases, although they are ætiologically and anatomically distinct. We can diagnosticate the enlargement of the heart, its functional disturbance, and the intactness of its valves, but whether the substance of the heart is simply hypertrophied or is studded with the indurations of myocarditis, can only be suspected; it never can be decided with certainty. Arrhythmia of the pulse may exist, in spite of the lack of all indurations, and it may be absent in spite of extensive cicatricial formation.

We may often enough find that the autopsy confirms our hypothesis of myocarditis, made from the ætiological factors, from the evidence of atheroma in the external arteries, from the existing cardiac insufficiency, and from certain characteristic symptoms like stenocardiac attacks and sudden death; but just as often, even with extensive clinical and pathological experience, we shall have to admit diagnostic errors and confusion between chronic myocarditis and simple cardiac hypertrophy.

**Treatment.**—The principles of the treatment of idiopathic cardiac hypertrophy are precisely the same as for valvular disease and myocarditis. We may therefore refer for all particulars to the two preceding chapters, and to the remarks upon the mechanical treatment of circulatory disturbances given at the close of the next chapter.

## CHAPTER V.

### FATTY HEART.

(*Cor adiposum. Fatty Degeneration of the Heart.*)

**Ætiology and Pathological Anatomy.**—By the name of "fatty heart" we often mean, at present, two quite distinct conditions of the heart—the one an abnormal deposit of fat in the heart, and the other a fatty degeneration of the muscular fibers of the heart. The first is usually one symptom of great general corpulency. At the autopsy of very fat people we sometimes find the heart entirely inclosed in a thick capsule of fat. The fat is situated chiefly in the external pericardium and beneath the visceral pericardium. It is usually very marked along the course of the larger vessels within the grooves of the heart, but in marked cases the fat also involves the muscular substance. The heart itself is otherwise quite normal or somewhat hypertrophied or dilated. There are sometimes also present sclerosis of the coronary arteries and indurations of myocarditis.

We have already mentioned fatty degeneration of the muscular substance of the heart as a frequent result of valvular disease. In myocarditis and idiopathic cardiac hypertrophy, and in the secondary hypertrophy after chronic nephritis and pulmonary emphysema, we also meet with fatty degeneration. We often find it, as well as fatty degeneration of other organs, in severe acute infectious diseases, in phosphorus poisoning, and in all marked primary and secondary anæmias. Under the microscope we find the muscular fibrillæ studded with little drops of fat, which may be so numerous that the nuclei and the transverse striation of the fibers are quite concealed by them. We often find, besides the fatty granules, albuminous granules, which disappear on the addition of acetic acid ("cloudy swelling" of the cardiac muscle). If the fatty degeneration is of high degree, we can easily recognize it with the naked eye. Beneath the endocardium, especially on the trabeculæ and papillary muscles, we see very fine and delicate yellow points and striæ. With great fatty degeneration, as in phosphorus poisoning and pernicious anæmia, the whole cardiac muscle is manifestly yellow, and also soft and flabby. It is claimed that rupture of the heart may occur as a result of marked fatty degeneration.

In fatty degeneration of the heart the fat comes from the decomposition of albumen in the muscular cells. The occasion of it is probably a defective supply of oxygen, which has either a general cause, as in anæmia and phosphorus poisoning, or a local cause, as disturbed circulation in the heart in heart disease. The details of this are given in the chapter on anæmia (page 928).

**Clinical Symptoms.**—Fatty degeneration of the heart has no special clinical

symptoms. In the conditions under which we know it is apt to occur we can usually suspect it during the lifetime of the patient, but we can not diagnosticate it. We must also mention that the frequently expressed opinion, that fatty degeneration of the heart is the cause of general cardiac weakness, is very often incorrect. In pernicious anaemia there may be quite a strong and a perfectly regular pulse up to death in spite of the most marked fatty degeneration.

We can not say much that is certain in regard to the clinical symptoms of a deposit of fat in the heart. "Fatty degeneration of the heart" always plays a far larger part in popular speech than it does in reality. It is certainly a fact that difficulty with the heart and respiration is very often observed in fat people. Examination of the heart, which, however, is decidedly impeded by the thick panniculus adiposus, often shows in such cases an increase of the cardiac dullness, a small and sometimes irregular pulse, and faint but clear heart-sounds. The disturbance may be very considerable, attacks of angina pectoris and cardiac asthma may come on, and death may follow with increasing dyspnoea and general oedema.

If one has opportunity to make an autopsy in such cases, there will be found no constant, single anatomical change as the cause of the cardiac disturbance, but either idiopathic cardiac hypertrophy (see the preceding chapter), or so-called myocarditic changes with sclerosis of the coronary arteries and the like. Very often there is, of course, a marked deposit of fat upon the heart itself, but the question arises whether this can directly and seriously embarrass the cardiac activity. The fact is that we often have seen similar well marked cases of fatty heart which during life presented no special cardiac symptoms. There would be more reason in ascribing an unfavorable influence to the fatty infiltration of the cardiac muscle; but here there is probably in most cases a simultaneous atrophy of the muscular tissue.

Therefore we can not associate with the term "fatty heart" any uniform clinical conception. It would be better to speak of the "heart of obesity," that is, of all the manifold injuries to which the heart of obese persons is exposed.

**Treatment.**—A great part of the disturbance in respiration in fat people depends not upon the cardiac weakness, but on the corpulency itself. The great bulk of the body, and the hindrance to the activity of the respiratory muscles, are very important factors. Treatment directed against the respiratory disturbance must hence chiefly attack the obesity, and thus in many cases we also assist the action of the heart. The detailed description of the hygienic methods of cure to be employed here is to be found in the chapter on obesity (page 996).

In regard to the special treatment of the cardiac symptoms, this does not differ from the rules that obtain in other forms of heart disease.

## APPENDIX.

### REMARKS UPON THE SO-CALLED MECHANICAL TREATMENT OF CIRCULATORY DERANGEMENTS.

Of late years, particularly since the publication of Oertel's views, so much has been written and spoken about the mechanical treatment of circulatory derangements in heart disease, obesity, and changes in the pulmonary circulation (such as those caused by emphysema, kyphoscoliosis, and the like), that it seems necessary to consider briefly here the chief points of this mode of treatment. There can be no doubt that in all the diseased conditions just named the disturbance of the circulation is one of the main causes of the clinical symptoms. The symptoms dependent upon the venous stasis are repeated in all the diseases which belong in this group, in almost the same way in every case (see their description on pages

295 *et seq.*). Inasmuch, however, as the disturbance may be essentially referred to mechanical influences, above all to the diminution of the difference between the arterial and the venous pressure, and the consequent slowing of the current and abnormal distribution of the blood, it is eminently proper to endeavor by mechanical means, so far as practicable, to improve the circulation. The possible points of attack are as follows:

1. *Diminution of the Body Weight when this has become Excessive from the Deposit of Fat.*—We shall, in a later chapter (page 992), study carefully the injurious influence of obesity upon the circulation. All the measures which lead to the diminution of corpulence, and which are to be carefully discussed later on, may therefore be of the greatest benefit in the treatment of circulatory disturbances in suitable cases.

2. *Diminution of the Amount of Liquid in the Body*—"Desiccation."—This is the point upon which Oertel lays the greatest stress. He believes that he can diminish the amount of blood in the body by withdrawing liquids, and thus lighten the task of the heart and restore the normal circulation. On this view rest the proscription of excessive drinking and the limitation of liquid nourishment, such as soup. We must confess that it is difficult for us to decide upon this point. Numerous well-known physiological experiments prove that the body maintains its amount of blood with great tenacity at a certain constant ratio. Inasmuch as the body is able by means of numerous ways (secretion and diffusion of liquids) to make speedy compensation for variations arising through changes in the amount of water ingested, it is by no means proved that the total amount of blood in patients with circulatory derangements is increased; and if actually there is a retention of fluid in the body (as indeed is certainly the case where oedema has developed), yet the liquid does not collect in the vessels, but in the lymph-spaces of the interstitial tissue, or possibly in the cells of the parenchyma itself. That the total amount of water in the system may be subjected to great variations must certainly be admitted; but that there should be any increase of the labor demanded of the heart, requires that a large amount of fluid should be added to the blood in a relatively short space of time, so that an actual, although extremely temporary, hydræmic plethora should exist. If this process is very frequently repeated, it will surely result in a permanent hindrance to the circulation. However, it is probable that this is the case only in habitual beer-drinkers, and that in such persons the proscription of liquid ingesta is of great value, because the patient is thus kept not merely from water, but also from the injurious and excessive use of beer and wine. Another way in which this limitation of drinking is of still wider practical importance is that a patient who is not allowed to drink while he is eating consequently eats less, and because he is not allowed to drink until after he has finished eating is furthermore, for that very reason, likely to drink less than he otherwise would. What might be called the "psychological importance" of the much-discussed prescription to abstain from liquids ought not therefore to be contested; but in our opinion this is its main value. In lean patients who live temperately the amount of liquids taken does not demand any special attention from the physician.

3. *Strengthening of the Cardiac Muscle and Promotion of Compensatory Hypertrophy.*—That the fulfilling of this indication may be of great importance is certain, and Oertel lays the greatest stress upon inciting the heart to more vigorous contractions by means of suitable bodily exertion, and especially by methodical mountain-climbing, in order by these means to promote as much as possible the development of cardiac hypertrophy. This view is probably fully justified and of obvious utility in many cases of simple cardiac weakness, as seen in anæmia, in convalescence from severe disease, and sometimes perhaps as a con-

genital condition. This may also be true, in many cases, of purely muscular disease of the heart; but as soon as one considers it in relation to those cases of circulatory disturbance where there is actual mechanical hindrance to the circulation, as from valvular lesions, the case seems wholly different. To be sure, one might have an idea that, by increasing the activity of the heart, the hindrance would be more easily overcome. An important consideration, however, seems to us to be that we can scarcely transfer our conceptions with regard to exercise and invigoration from the voluntary muscles to the cardiac muscle. The mechanically dilated heart is minutely regulated by means of an especial reflex apparatus, independently of our volition. We know that every increased demand upon the heart's activity is in most cases directly fulfilled by an increased cardiac effort. Under proper conditions the most marked cardiac hypertrophy may develop in a completely bedridden patient. We must therefore consider carefully whether, in cases of this sort, the further increase of the demands upon the heart is judicious; whether it may not, on the contrary, contribute to a premature exhaustion of the myocardium. It certainly seems to us, and our opinion is fortified by practical experience, that the prescription of increased bodily exertion, such as mountain-climbing, should always be given with great caution, and with consideration of the individual circumstances, if the physician desires to avoid unhappy consequences. We share the belief that a certain measure of bodily exercise is very suitable for patients with valvular and other similar cardiac lesions, but we hold that the benefit lies less in the resultant "invigoration of the cardiac muscle" than in the promotion of the venous circulation occasioned by the motion of the extremities and the deeper inspirations (see page 998). Long mountain trips have a great and unique value for those circulatory disturbances alone which are occasioned by obesity, or associated with simple weakness and slight dilatation of the heart.

4. *Promotion of the Circulation by Massage, Passive Movements, and Gymnastics.*—It can not be doubted that these are suitable means for the promotion of the circulation, especially in the veins. We ought not to overestimate their value, but we are fully justified in the assertion that they may sometimes be employed with decided benefit in circulatory derangements. For particulars as to the carrying out of this method of treatment, we must refer to appropriate monographs.

## CHAPTER VI.

### NEUROSES OF THE HEART.

1. *Angina Pectoris (Stenocardia).*—Angina pectoris is a group of symptoms which we have already had to mention repeatedly as a frequent complication in different cardiac affections, such as indurated myocarditis, aortic insufficiency, etc. The same symptoms are also seen as a pure neurosis, especially in anæmic persons, or in connection with other nervous diseases, like hysteria, epilepsy, and the psychoses. We know almost nothing as to the exact ætiology of the disease. In quite a large number of published cases excessive smoking has been advanced as an ætiological factor.

The most essential symptom of the paroxysm consists in a severe pain in the cardiac region, shooting up into the left, or, more rarely, into the right shoulder. There is also a general feeling of constraint and anxiety—"precordial anxiety." The action of the heart is usually somewhat accelerated, either weak and perhaps intermittent, or strong. Respiration is unimpeded. Exceptionally, however, and probably as a result of the pain, it becomes irregular, now hurried and now slow.

The skin during the paroxysm is often pale and cool, while at the end of it there may be profuse sweating. The individual attack lasts sometimes only a few minutes, and sometimes half an hour or more. In many cases the paroxysms return very frequently, almost daily, but in others there may be intervals of weeks or months.

Many theories have been advanced as to the nature of angina pectoris, but none of them have any certain foundation. Since the sensory fibers of the heart rise from the vagus (but partly, perhaps, from the sympathetic also), we usually term angina pectoris a neurosis of the vagus.

The prognosis of the disease is not very favorable. Although life itself is very rarely endangered by the paroxysms, we seldom succeed in permanently preventing their return.

The treatment of the paroxysm is purely symptomatic. Cutaneous irritants, like mustard-plasters to the chest, and foot-baths, are almost always used, but they have but little effect. A subcutaneous injection of one sixth to one third of a grain of morphine (grm. 0·01-0·02) is the best palliative. All the other remedies, like nitrite of amyl, inhalations of chloroform, atropine, coniine, etc., are less reliable. Nitrite of sodium has been especially recommended.

Many remedies have also been used to prevent the return of the paroxysms: arsenic, sulphate of zinc, nitrate of silver, bromide of potassium, quinine, etc. We usually try one of these remedies, but without promising any certain benefit from them. Favorable results are often obtained from electrical treatment—either the application of the faradic brush to the cardiac region, or cautious galvanization of the vagus and sympathetic in the neck, or in the cardiac region. Methodical cold-water cures have also resulted in improvement in some cases of angina pectoris.

Finally, of course, we must pay attention to any underlying diseases, like anæmia and epilepsy, and to the removal of injurious influences which may affect the disease (smoking!).

[In well-marked angina sudden death during a paroxysm is not very rare. In Dr. Arnold, of Rugby, the first attack proved fatal. The patient may, however, live for years—cases of survival for upward of twenty, and one even of thirty, years being recorded. Flint has known recovery to occur. The prognosis depends somewhat on the condition of the cardiac valves and walls; but changes, especially in the latter, may escape detection by any save a very skillful observer. Walshe states that in every one of twenty-four cases he examined during life he found physical signs of changes either in the heart, the aorta, or both. The experience of Balfour and Latham is similar.

With regard to treatment, it is true that morphine, subcutaneously, brings relief; but the duration of the attack is short, the physician is not always at hand, and there are scarcely any circumstances under which it is right to arm a patient with a hypodermic syringe in this any more than in other diseases.

Nitro-glycerine is not only a palliative in most, but also a prophylactic in many cases. To cut short an attack, it can be carried in the pocket; to prevent recurrence, it can be taken twice or thrice daily. The nitrite of sodium seems to act equally well, but has not been so long in use. The nitrite of amyl is serviceable chiefly at the moment of attack. It is put up in glass capsules, one of which can be crushed in a handkerchief and the contents inhaled; it is so volatile that it can be preserved ready for use in scarcely any other way.

The value of the nitrites is greater than the author would seem to allow.]

**2. Nervous Palpitation.**—By "palpitation" we understand the subjective sensation of the movements of the heart. It is usually excited by increased action of the heart, but there is no constant relation between the intensity of the cardiac

pulsations and the subjective feeling of them. We sometimes observe that patients with aortic insufficiency do not perceive the very strong action of their hypertrophied hearts, while in other cases a patient complains of a troublesome feeling of palpitation, although the action of the heart does not appear objectively to be especially increased.

We term cases "nervous palpitation" where the patient complains of palpitation when a physical examination of the heart shows no anatomical change in it. As a rule, in these cases we really have to do with a heart whose action is increased by abnormal nervous influences. In many cases the palpitation arises from slight external causes, which may give rise to little or no palpitation in a healthy person, as, for example, after the slightest mental excitement, after any slight physical exertion, after taking food, after indulging in certain drinks, like tea, coffee, wine, or beer, or in certain positions of the body, as in lying on the left side. Here, then, we have to do with an abnormal sensitiveness of the heart to external irritation, but in other cases there is probably a kind of hyperæsthesia of the patient to the movements of the heart, so that the movements that are of normal strength are felt in a troublesome manner.

The patient rarely complains of continuous palpitation; it usually occurs in more or less sharply defined paroxysms. Very commonly in pure nervous palpitation we have to do with people who, in general, suffer from other nervous, hysterical, and neurasthenic symptoms, or they are anæmic persons, chlorotic girls, etc.; but, on the other hand, nervous palpitation may occur in very full-blooded, "plethoric" people.

The diagnosis of nervous palpitation can be made only when repeated careful examination shows no objective abnormality in the heart. In many cases, as when there are anæmic murmurs, the decision may be quite difficult. We must always pay particular attention to the whole constitution and the general impression which the patient makes.

The prognosis is so far favorable in that the disease is not dangerous. In many cases improvement and final recovery may be effected, but other cases, of course, resist all therapeutic efforts very obstinately.

The treatment must first be directed to improving the patient's general constitution. Anæmic persons are to be given iron, quinine, and strengthening diet. We put full-blooded people, however, on scanty fare, and prescribe for them bitter waters, or a bath cure at Marienbad or Kissingen. Where there is hysteria or neurasthenia, it requires special treatment. We should avoid all the influences which seem to excite palpitation. As a symptomatic indication during an attack we should recommend the patient especially to keep quiet. The use of cold to the cardiac region—cold compresses and ice-bags—often acts beneficially. On the other hand, however, it is to be noted that a tendency to palpitation associated with cardiac weakness may often be allayed by methodical exercise and the invigoration of the cardiac muscle consequent thereupon (see the appendix to the preceding chapter). Among internal remedies we must employ nervines, and in severer cases even narcotics. Among the former we would mention especially ethereal tincture of valerian and bromide of potassium, which have repeatedly done us good service. Digitalis is usually of little value in pure neuroses of the heart, but we may give it as an experiment, say fifteen to twenty drops of the tincture with the same amount of cherry-laurel water.

3. **Tachycardia.**—A peculiar and quite rare neurosis of the heart, tachycardia, consists of an enormous frequency of the pulse, coming on in paroxysms, up to 200 beats and more a minute. We have already mentioned these paroxysms as a rare symptom in mitral and also in aortic disease, but precisely similar attacks may occur as a pure neurosis without any discoverable lesion of the heart. They

have been observed in anæmic and nervous, and also in corpulent persons. In young people the same condition sometimes occurs after diphtheria and other acute infectious diseases (*vide supra*). In men we must consider the possibility of the action of injurious dietetic influences, like drinking and smoking. The individual attack usually begins quite suddenly, by day or by night, sometimes without any cause, but often it is apparently produced by certain exciting causes, especially at times by overdistention of the stomach. The patient feels that the attack is coming, he becomes anxious and restless, and looks pale; but there are not, as a rule, at least according to our experience, any symptoms like præcordial anxiety, dyspnœa, or attacks of faintness. We notice in the heart itself, during the attack, chiefly a great acceleration of the heart-sounds. We sometimes hear indefinite, adventitious murmurs. The action of the heart is often quite regular, but there is not infrequently manifest arrhythmia during the attack. Increase of the heart's dullness has been repeatedly observed. In a case of paroxysmal tachycardia, in a patient who had cirrhosis of the liver, we could certainly detect a considerable acute dilatation of the heart in every attack, which disappeared again soon after.

We know little that is definite as to the nature of the attacks. The affection is usually regarded as a temporary paralysis of the vagus.

We may also state here that paroxysmal and constant tachycardia have also been repeatedly observed in anatomical lesions of the cardiac nerves and their centers, in tumors and other affections in the vicinity of the medulla oblongata, and in compression of the vagus in the neck from new-growths, and aneurisms.

The prognosis of tachycardia depends first upon the nature of the underlying disease. We do not know whether a permanent recovery is possible in idiopathic cases, but we can always succeed in improving the condition. The treatment during the attack consists in enjoining complete bodily rest, and in applying ice to the heart. With marked subjective disturbance we should give bromide of potassium, or even, under some circumstances, a small injection of morphine. The best way to guard against the return of the attacks is to give precise hygienic directions, suited to the patient's constitution and manner of life. The continued use of iodide of potassium has sometimes seemed to us to be of service.

## SECTION II.

### DISEASES OF THE PERICARDIUM.

#### CHAPTER I.

#### PERICARDITIS.

(*Inflammation of the Pericardium.*)

**Ætiology.**—Pericarditis seldom appears as a primary idiopathic disease. It is usually merely a sequel or a complication of other diseases. Thus, it is observed with particular frequency in the course of acute articular rheumatism, where it appears sometimes alone, sometimes in combination with acute endocarditis. It is not impossible that certain rare cases of apparently primary acute pericarditis belong, from an ætiological standpoint, to acute articular rheumatism—that is, they are excited by the same pathogenic factors which exceptionally attack the pericardium alone, without simultaneous participation of the joints in the disease.

It must be confessed that this view is not actually proved to be correct, although a similar one is also held in regard to many cases of primary acute endocarditis. Cases of secondary pericarditis, unassociated with articular rheumatism, occur, although much less often, in other acute infectious diseases, among which scarlet fever, measles, and pyæmic processes, as well as scurvy and purpura hæmorrhagica, deserve especial mention. In pyæmia the pericarditis is purulent, and in purpura, hæmorrhagic. Among the chronic diseases in the course of which pericarditis sometimes appears, we must mention especially chronic nephritis. Pericarditis has also been observed in a few cases in patients with carcinoma.

A large number of cases arise from an extension of the inflammation from the vicinity. Thus we not infrequently see pericarditis as a result of pleurisy, especially on the left side, and in pneumonia complicated with pleurisy. New growths and ulcerative processes in the œsophagus, in the vertebræ, in the bronchial glands, or in the lungs, also lead at times to perforation into the pericardium and a consequent inflammation. The pericarditis, too, which not very rarely comes on in the course of chronic valvular disease, is probably usually to be regarded as an extension of the inflammation. As has already been mentioned, it is most frequent, according to our experience, in aortic disease, so that we may suspect a direct conduction of the agents of inflammation through the aortic walls into the pericardium. Pericarditis may also develop as a result of myocarditis, abscess of the heart, etc.

Tuberculosis plays a very important part in the ætiology of pericarditis. No small number of apparently primary cases of pericarditis turn out at the autopsy to be tubercular. This apparently comes on in quite an isolated way, or as one symptom of a special localized form of tuberculosis, which we term tuberculosis of the serous membranes. In many cases we can discover the origin of a tubercular pericarditis in the direct extension of a tubercular pleurisy. In apparently primary cases the occurrence of the infection may sometimes be explained by the discovery of a tubercular lymph-gland, which has broken through into the pericardium.

Pericarditis is usually a disease of youth and middle life, but it may also occur in advanced age.

**Pathological Anatomy.**—Ordinary pericarditis involves the two surfaces of the internal pericardium in either a circumscribed or diffuse manner. Inflammations of the outer surface of the pericardial sac are distinguished as external pericarditis (*vide infra*). The anatomical processes in pericarditis are precisely analogous to those in inflammations of the serous membranes in general, especially of the pleura.

We usually divide pericarditis into fibrinous, sero-fibrinous, hæmorrhagic, and purulent (or ichorous) forms, according to the character of the exudation. The fibrinous and sero-fibrinous forms, with an abundant fluid effusion into the pericardial cavity, are the most frequent, occurring in articular rheumatism, in valvular disease of the heart, etc. Both layers of the pericardium are covered with masses of fibrine, which often show a reticular or villous arrangement (*cor villosum*). Besides that, we find more or less of a fluid effusion which distends the pericardium. The fluid is of a serous nature, and contains more or less numerous flakes of fibrine, and is turbid from the admixture of cells—pus-corpuscles, and, in part, desquamated endothelium. A purulent pericarditis is always the expression of a specific infection of the pericardium. It is seen in pyæmic diseases, as a result of empyema, and in perforation of abscesses, cancers of the œsophagus, etc., into the pericardium. A hæmorrhagic effusion is seen chiefly in tubercular pericarditis. In this we find miliary tubercles, and little cheesy nodules in the inflammatory new growths, besides all the signs of inflammation. The specific

tubercular changes are sometimes recognizable with the naked eye, but at other times we have to use the microscope to find them. Hæmorrhagic pericarditis also occurs in general hæmorrhagic diseases, such as scurvy, and in weak and debilitated people, like drunkards.

In long-continued pericarditis the cardiac muscle almost invariably undergoes changes. The heart is usually flabby and dilated, and the muscle often shows fatty degeneration. After the pericarditis has lasted a long time there is often quite a considerable atrophy of the cardiac muscle, which is partly replaced by fat tissue. We have already mentioned the occurrence of pericarditis in connection with valvular disease and degenerations of the myocardium.

In favorable cases of pericarditis we may have a perfect recovery. The so-called *maculæ tendineæ* sometimes remain in the pericardium as residua of a past circumscribed pericarditis. In some cases the pericarditis leads to an adhesion of the two layers of the pericardium to each other, and obliteration of the pericardial cavity (*vide infra*). In many cases a chronic pericarditis finally develops from the acute form, or the whole affection takes a more chronic course from the outset. In this way chronic adhesions of connective tissue arise, and great thickening of the pericardium, but the amount of fluid is usually small. Sometimes the chronic pericarditis is interrupted by an acute exacerbation of the disease.

**Clinical Symptoms.**—1. *Subjective Symptoms, General Symptoms, and Fever.*—Mild forms of pericarditis may develop, as in the course of an acute articular rheumatism, without causing any subjective symptoms. They are discovered only by a careful physical examination of the heart. In severe cases, however, the pericarditis causes violent subjective symptoms, which of course have in themselves little that is characteristic.

Pain may be felt in the cardiac region, and often in the epigastrium, but it is absent in very many cases. A general feeling of constraint and distress is almost constant in all acute cases of any severity, and so is a feeling of dyspnoea, which may increase to the highest degree of orthopnoea. The patients often complain of headache. In severe cases they become stupid and comatose.

These general symptoms are the direct result of the disturbance of the circulation. Blood pours into the heart slowly, and the diastole is incomplete, because of the increased pressure in the pericardium. Although stasis occurs in the veins, there is less blood in the right ventricle than normal. As a result of this the pressure falls, and the rapidity of the current in the pulmonary circulation diminishes. The left ventricle, also, contains too little blood, and the tension in the medium-sized arteries is considerably lowered. This is the explanation of the patient's dyspnoea and cerebral anæmia. The former is also increased in large pericardial effusions by the mechanical pressure of the distended pericardium on the left lung.

Acute pericarditis is usually associated with fever. This has no special type, and usually keeps at a moderate height— $102^{\circ}$  to  $103.5^{\circ}$  ( $39^{\circ}$ – $39.8^{\circ}$  C.)—but it often exhibits considerable variations. In cases of recovery the fever declines by lysis. Chronic pericarditis may run its whole course without fever.

2. *Physical Signs—Inspection.*—The general hue of a patient with severe pericarditis is pale, but also more or less cyanotic. He has an anxious expression. He lies with the upper part of the body raised, or he sits up in bed. The breathing is usually rapid, labored, and somewhat irregular. The veins in the neck are swollen and prominent. We very often see marked undulating or pulsating movements in the jugular veins, as a result of stasis. The cardiac region seems unusually prominent in all cases with much effusion, and the intercostal spaces there are flattened out. We sometimes detect a slight œdematous swelling of the

chest-wall itself. When there is a large effusion, the action of the heart is only faintly visible, and is sometimes remarkably diffused.

Palpation in the milder cases shows the apex-beat in its normal position and of about normal strength; but if the amount of the pericardial effusion increases, the heart is pushed away from the chest-wall by it, and hence the heart-beat grows weaker until it disappears entirely. In such cases it is sometimes to be felt again if the patient bends forward or lies on his left side. In the rest of the cardiac region we sometimes feel the movements feebly, but they entirely disappear as the effusion increases. In some cases, by laying the hand flat on the chest, we can feel the rub of the rough pericardial surfaces against each other.

The pulse is usually accelerated, and in severe cases it becomes irregular. In every large effusion, as we have already said, the tension and height of the pulse are diminished. In severe cases the pulse sometimes becomes very small and weak, but, when the heart is otherwise normal and strong, it may also remain quite strong—and indeed this condition of the pulse, in contrast to the great weakening of the heart-beat, is sometimes of diagnostic significance. In some cases with a large pericardial effusion we have seen a manifest *pulsus paradoxus*—that is, a diminution or a complete disappearance of the radial pulse on every inspiration.

Percussion shows very characteristic changes if the pericardium is distended by the effusion. The cardiac dullness is then increased, and usually assumes a triangular form peculiar to pericarditis. The obtuse angle of the triangle is found above in the third or second left intercostal space near the left border of the sternum. The lateral boundaries run obliquely to the right and downward to about the right parasternal line, and to the left and downward to the left mammillary line, or beyond. The broad base of the triangle which lies below is usually not to be defined by percussion on account of the adjacent left lobe of the liver. On the border of the dullness we often find a tympanitic resonance due to the retraction of the adjacent lung. The area of the dullness depends, of course, in the first place, upon the amount of the effusion, but we must take special notice that in regard to this the relation is not constant. In old cases of pericarditis especially we sometimes find the cardiac dullness very extensive, while the autopsy detects only a little fluid in the pericardium. This is explained partly by a secondary dilatation of the heart, and partly by a persistent retraction of the lung.

It is an important diagnostic sign of pericarditis that in many cases the still perceptible apex-beat lies within the cardiac dullness, since the pericardial effusion extends farther to the left than the heart itself. It is also worthy of note that the dullness in pericarditis often shows very great changes when the patient changes his position. The dullness is more extensive when the body is erect than when lying down, and when the patient lies on his side it sometimes shows a lateral displacement of several centimetres. The same changes, however, though rarely so marked, also occur in a hypertrophied heart.

The characteristic pathognomonic auscultatory sign of pericarditis is the pericardial friction-rub. This arises during the movements of the heart from the rubbing of the rough and inflamed pericardial surfaces against each other. The friction-rub is absent in pericarditis if the rough surfaces of the two layers of the pericardium are separated from each other by a fluid effusion, or if they can no longer rub against each other from an adhesion of the layers of the pericardium. We usually hear the friction-rub loudest in the neighborhood of the base of the heart, but it may also be heard at other parts of the heart. The quality of the sound is described as scraping, grating, or creaking. The friction-rub may be heard chiefly either during the systole or during the diastole of the heart, but it is in general not often closely associated with the phases of the heart's action. We sometimes find it intermitting frequently, and jerky. The intensity of the fric-

tion-rub sometimes varies with the phases of the respiration. It is usually louder on inspiration, but sometimes on expiration. If the patient changes his position, it sometimes alters the intensity of the sound. It is louder when sitting up than lying down, etc. The friction-rub often sounds louder if the stethoscope is pressed firmly against the chest, since in this way the layers of the pericardium are approximated to each other.

The heart-sounds, when the valves are intact, may sometimes be heard as well as the friction-rub, or they may be completely drowned by the loud rub, at least in some parts of the heart. In general, they are weak in every case of pericardial effusion, since their conduction to the ear is impaired. In large effusions where no friction-rub is to be heard, we hear the heart-sounds, especially the first, but only very faintly and obscurely. This condition in connection with the increase of the cardiac dullness is of diagnostic importance. If there is also valvular disease with the pericarditis, the pericardial and endocardial murmurs are sometimes hard to distinguish from each other, but usually the former greatly preponderate.

3. *Sequelæ of Pericarditis.*—A large pericardial effusion may excite special symptoms from pressure on the neighboring organs. Thus we have already said that compression of the left lung must increase the dyspnoea. In many cases we also notice a moderate dullness over the left lower back, from compression of the left lower lobe. In rare cases difficulty in deglutition has been observed as a result of pressure on the œsophagus, and paralysis of the vocal cords from pressure on the recurrent nerve.

In cases of long-continued pericarditis the same sequelæ may develop as in any chronic disease of the heart. The amount of urine diminishes as a result of the low arterial pressure. The venous stasis finally leads to general dropsy and to symptoms of passive congestion in the liver, spleen, and kidneys. We would also state that we have repeatedly met with large effusions in the cavities of the body, especially hydrothorax, without any œdema of the skin. All the symptoms of stasis mentioned, however, are often much less due to the pericarditis itself than to the atrophy and dilatation of the heart which frequently follow it (*vide supra*).

#### SPECIAL FORMS OF PERICARDITIS.

1. **Pericarditis externa and Mediastino-pericarditis** (*Pleuro-pericarditis*).—By pericarditis externa we mean an inflammation of the external surface of the pericardial sac, which is usually combined with an inflammation of the mediastinal connective tissue and the neighboring pleura, especially over the lingula of the left lung. This form of pericarditis may exist by itself, or combined with internal pericarditis. It is a rare disease, and is most frequently seen as a result of tubercular pleurisy.

The physical signs must differ so much, according to the localization and extent of the process, that we can give few general data in regard to them. There are only a few peculiar signs, which must be noted as characteristic of many cases. In the vicinity of the apex-beat, or at the left border of the cardiac dullness, we sometimes hear a so-called extra-pericardial (pleuro-pericardial) friction-rub. This depends both upon the cardiac movements and upon the respiratory movements. On holding the breath we hear only the murmur due to the pulsations of the heart, while on deep breathing the pleuritic friction-sound is chiefly to be heard. In individual cases there are many modifications, which can not all be mentioned. Another interesting sign, first found by Griesinger and Kussmaul in a cicatricial mediastino-pericarditis, is the so-called *pulsus paradoxus*. This consists of a diminution of the pulse at each inspiration. This condition arises, in part of the cases at least, from the fact that the bands and adhesions of connective tissue at the

origin of the aorta mechanically nick into and contract its lumen at every inspiratory movement of the thorax. This explanation, of course, does not suffice for all cases, since the *pulsus paradoxus* also occurs under other conditions, as with large pericardial effusions. In some cases there may be seen a marked swelling of the jugular veins in the neck at each inspiration, at the same time with the *pulsus paradoxus*, since the large venous trunks also undergo a mechanical nicking and constriction at each inspiration. We have ourselves seen a very pronounced slowing of the pulse at every inspiration, in a complicated case of extra-pericardial adhesions (vagus irritation?). We must also mention that Riegel observed a disappearance of the apex-beat on expiration in some cases where there were bands of connective tissue between the lungs and the outer surface of the heart. At every expiration the bands were stretched more tightly, and hence checked the movements of the heart.

**2. Obliteration of the Pericardial Cavity** (*Adhesive Pericarditis; Adhesions of the Layers of the Pericardium; Concretio seu Synechia pericardii*).—We may have a more or less complete adhesion of the two layers of the pericardium with each other as a result of pericarditis. We can sometimes observe the occurrence of this condition during the course of a pericarditis. Quite frequently, however, we meet with extensive adhesions of the two layers of the pericardium on the living subject, or at autopsies, without being able to gather any history of a previous acute pericarditis. The pericarditis must have occurred here in a chronic way, and without symptoms from the outset.

Even extensive adhesions of the pericardial surfaces may develop and remain entirely without symptoms, and be met with accidentally at the autopsy. In other cases, however, the obliteration of the pericardial sac causes special physical signs and severe clinical sequelæ. Among the first and more important is the systolic retraction of the chest, either limited to the apex or involving a larger area. This is most comprehensible if there is an adhesion of the pericardium with the heart, and also with the chest-wall (Skoda); but we certainly find this retraction at the systole without co-existing extra-pericardial adhesions. It is not, however, an absolutely certain sign of an intra-pericardial adhesion, especially if we have to do with a systolic retraction at the apex alone, since systolic retractions may sometimes occur in other disturbances of the heart's motions; but systolic retractions of the whole cardiac region are, in the majority of cases, a certain sign of pericardial adhesions. The amount of this retraction is often dependent upon the respiration, it being usually more marked on inspiration.

The other symptoms of obliteration of the pericardial cavity are more rare and in their diagnostic significance still more uncertain. Friedreich observed a sudden collapse of the jugular veins at each diastole—the “diastolic collapse”—while they became well filled again at the next systole. He explained this phenomenon by supposing that the conditions for emptying the veins, at the moment of the diastole of the ventricle, were especially favorable, since the chest-wall, which had previously been drawn in by the systole, went back again quickly. Riess described some cases of pericardial adhesions where the heart-sounds had a metallic character from the resonance of the stomach, which had been drawn up. All things considered, we must say that although the diagnosis of pericardial adhesions can be correctly made in many cases, yet the signs given for it are more or less uncertain, since they may be absent in obliteration of the pericardial sac, and they may also be caused by other conditions without such an obliteration.

In the cases of pericardial adhesions which give rise to severe disturbances of the circulation, these are usually not the direct result of the pericardial adhesions, but are due to the secondary changes which develop in the cardiac muscle. Only when extensive extra-pericardial adhesions are also present can there be

such a restraint upon the systole of the heart, in a purely mechanical way, as to cause a diminished filling of the arteries, and stasis in the veins. It is usually, however, the secondary atrophy, with fatty degeneration and dilatation of the cardiac muscle, that causes the severe disturbances of the circulation. Such cases give throughout the general impression of valvular disease. Dyspnoea, general oedema, and signs of passive congestion in the liver and kidneys, are the chief symptoms of the disease. It is a striking observation, which other physicians and we ourselves have made a few times, that as a result of obliteration of the pericardial sac, great ascites, sometimes associated with hydrothorax, may develop without any simultaneous oedema of the extremities. In all such cases the diagnosis is usually far from easy. We can sometimes scarcely avoid confounding it with chronic myocarditis, in the absence of all heart-murmurs. If the cardiac muscle remains intact, extensive pericardial adhesions may exist for years without causing the patient the slightest disturbance.

**3. Tubercular Pericarditis.**—Tubercular pericarditis is an important disease clinically, since in many cases it is apparently primary. It may be either quite acute or chronic. The patient falls ill suddenly, or more gradually with indefinite thoracic symptoms, dyspnoea, general weakness, moderate fever, etc. If it is of long duration, there is more or less oedema. When we find on physical examination, in such cases, the signs of a pericarditis, the diagnosis of tubercular pericarditis is probable, if we discover a general "phthisical habit," hereditary predisposition, and also co-existing disease of other serous membranes, especially pleurisy, or more rarely chronic peritonitis. In the latter case the tubercular pericarditis forms one symptom of the so-called tuberculosis of the serous membranes, but, as has been said before, apparently isolated primary tubercular pericarditis does occur (*vide supra*). We have seen such cases repeatedly, especially in old people. In these cases the disease is not easy to diagnosticate. The patient gives one the impression of having heart disease, but the physical signs in the heart are sometimes of a very indefinite nature. Friction-rubs may be entirely absent, on account of adhesions or of large effusions. This leads to confusion with myocarditis, or mitral stenosis. In other cases, of course, all the physical signs of pericarditis mentioned above may be manifest, and a correct diagnosis can be made.

**Diagnosis.**—From what precedes, it follows that the diagnosis of pericarditis is very easy in many cases, but is very difficult or impossible in others. The most unequivocal sign is the characteristic friction-rub. The practiced ear can often distinguish it from an endocardial sound by its quality. The pericardial sound is a rubbing, grating noise, near the ear; the endocardial is blowing, distant from the ear. The following features may serve as marks of distinction in doubtful cases: 1. We hear the pericardial sounds at first, and also later, over the base of the heart in the vicinity of the pulmonary valve; the endocardial are often loudest at the apex. 2. The pericardial murmurs are not so closely associated with the phases of the heart's action, with systole and diastole, as the endocardial. 3. We find that the pericardial sounds are not transmitted far. A loud rub may be audible at one spot which can not be heard a few centimetres away. Loud endocardial murmurs, however, are audible over almost the whole heart. 4. Sometimes the peculiarity of the pericardial murmur—that it becomes louder when the patient sits up, on pressure with the stethoscope, etc.—may be of diagnostic value. In many cases, too, the loud, functional, so-called anæmic murmurs over the base of the heart may give rise to confusion with pericarditis.

In the cases where pericardial sounds are absent the diagnosis is rendered possible by the characteristic triangular shape of the cardiac dullness, in connection with the character of the apex-beat, the pulse, and the heart-sounds. We have

already called attention to the ease with which pericarditis may be confounded with myodegeneration of the heart and mitral stenosis without any murmur. We can not lay down general rules for differentiating these conditions. The more careful the examination, and the greater the personal experience, the more easily can we avoid a false diagnosis.

We have already mentioned the determining factors for the diagnosis of the different forms of pericarditis and their significance.

**Course and Prognosis.**—Many cases of pericarditis in articular rheumatism, pneumonia, or heart disease, and also many of the rare and apparently primary forms, may recover completely. The disease lasts, in the mild cases, only about a week, in severe cases much longer.

Many cases of pericarditis, however, terminate fatally. The unfavorable issue depends either upon the severity of the primary disease, or upon the intensity of the pericarditis itself. In extensive croupous pneumonia, in valvular disease of the heart, or in severe chronic nephritis, an attack of pericarditis is often the terminal affection—the immediate cause of death. In otherwise healthy people, however, a severe pericarditis with a large effusion may be the direct cause of death, as a result of the impairment of the movements of the heart. The prognosis of every tubercular pericarditis is absolutely unfavorable. The latter can, indeed, run quite a chronic course, but it is hardly ever capable of definite recovery. The prognosis of pyæmic pericarditis is also unfavorable.

In one class of cases pericarditis takes a chronic course from the start, or chronic pericarditis develops from an acute attack. The ultimate prognosis of these cases is usually unfavorable, since the secondary atrophy and dilatation of the heart gradually lead to severe disturbances of the circulation. We have spoken above of the termination of pericarditis in obliteration of the pericardial sac.

**Treatment.**—Since pericarditis is a severe affection under all circumstances, we must especially see that the patient has perfect rest and care. Extreme caution must be enjoined upon him, especially in the cases where at first the subjective symptoms are slight. We must keep the patient strictly confined to the bed, and not let him leave it even temporarily.

The remedies which are used against pericarditis aim partly at keeping the inflammation in check, and partly at aiding the action of the heart. For the first, the continued application of ice to the cardiac region deserves especially to be recommended. Local blood-letting, ten or twelve leeches to the cardiac region—formerly very often but now more rarely used—may, in otherwise strong and healthy persons, afford great relief in cases with marked subjective symptoms. Painting with tincture of iodine and vesicatories, however, deserve little confidence. Digitalis is our chief means to bring down an accelerated pulse, and to strengthen the heart's action. It is a drug which is most active and most frequently used in pericarditis, and is always indicated when the pulse is rapid and of diminished tension. Of course, the action of the remedy must be carefully watched, as in all cases where digitalis is prescribed. Tincture of strophanthus is also useful. As a palliative, morphine often does indispensable service where the subjective symptoms are marked and the patient is very restless.

If the symptoms are threatening, the question arises whether a large fluid pericardial effusion is the cause of the severe symptoms. In this case the evacuation of the exudation is of course imperatively indicated. The difficulty of forming a correct opinion, however, is very great, because in any individual case it is rarely possible to determine the amount of fluid that may be present. In the first place, we must consider the size of the cardiac dullness and the weakening of the movements of the heart, but both factors may give rise to deception. Hence we always

first make an exploratory puncture with a Pravaz's hypodermic syringe. The best point for insertion is, in general, the sternal end of the fourth or fifth [left] intercostal space when the patient is lying on his back. If the exploratory puncture gives a positive result, we make a puncture with Billroth's, Fraentzel's, or some similar trocar. With regard to the details, we will refer to the description of puncture of the pleura. Puncture of the pericardium is always performed by the aid of aspiration. It is less dangerous than might be feared. Even injuries to the heart during the operation have scarcely ever had grave results. The temporary relief to the patient, in cases of successful puncture, is usually very striking, but the permanent results of pericardial puncture are, of course, much less favorable than those of puncture of the pleura, which is chiefly due to the character of the underlying disease. In some cases of purulent pericarditis, drainage of the pericardium has also been practiced after the analogy of the treatment of empyema, but experience on this point is not yet very extensive.

[The experiments of Rotch show that pericardial effusion causes dullness in the fifth right interspace, a sign which he thinks is not produced in cardiac enlargement. So far as is known to the editor, he is the only person who has acted on this observation, and punctured on the right of the sternum for pericardial effusion. In the case referred to, the signs pointed to a very large acute effusion of rheumatic origin. The first puncture was made in the fifth left interspace, but only about an ounce and a half of bloody serum was obtained. The needle was then withdrawn and immediately inserted in the fourth right space near the sternal border with absolutely negative result. The gravity of the symptoms led to two more punctures on the left some days later, one with small though positive result, the other with negative. Absorption and recovery ultimately took place.

The recommendation of the author to make a preliminary puncture with a hypodermic syringe for diagnostic purposes seems unnecessary, just as with pleural effusions.

Roberts has tabulated sixty cases of paracentesis of the pericardium, with twenty-four recoveries.]

If there is a condition of cardiac weakness, stimulants are indicated—strong wine, subcutaneous injections of ether or camphor, or wine of musk. We try to keep up the patient's strength by the best of nourishment.

The resulting conditions of disturbance of the circulation, like œdema, in chronic pericarditis, are treated in the same way as in valvular disease (*vide supra*). Digitalis, in small doses, and diuretics, are the chief remedies.

## CHAPTER II.

### HYDRO-PERICARDIUM, HÆMO-PERICARDIUM, AND PNEUMO-PERICARDIUM.

#### 1. Hydro-Pericardium.

(*Dropsy of the Pericardium.*)

THE collection of a serous transudation in the pericardial sac, without any inflammatory symptoms in the serous membrane itself, we term hydro-pericardium, or dropsy of the pericardium. Dropsy of the pericardium, which formerly played quite a great rôle in pathology, is never a disease of itself, but is always a secondary condition. It may occur in anæmic and cachectic people as a result of hydræmia, but it usually depends upon a local or general venous stasis in the pericardium. In the latter case the hydro-pericardium is one symptom of general

dropsy, and hence is found chiefly in heart disease, renal disease, or pulmonary emphysema.

The clinical symptoms of hydro-pericardium are only exceptionally distinct, being obscured by the underlying affection. Large amounts of fluid in the pericardial sac, which may amount to a quart (a litre) or more, must of course impair the action of the heart, weaken the heart-beat objectively, and cause an increase in the cardiac dullness. The distinction from pericarditis is rendered possible by the absence of a friction-rub, but especially by attention to the existence of an underlying disease. In other respects the distinction between a pericardial transudation and an effusion during life is not always easy.

The prognosis and treatment depend wholly upon the nature of the underlying disease. Only exceptionally do we need to puncture, when the exudation is very large.

### 2. Hæmo-Pericardium.

*(Blood in the Pericardial Sac.)*

In rare cases hæmorrhages occur into the pericardial sac. The source of the hæmorrhage is most frequently an aneurism of the aorta, which perforates into the pericardium. Other causes of hæmorrhage are the bursting of aneurisms of the coronary arteries and rupture of the heart. The latter has been seen after injuries, and also as a result of cardiac aneurism and the cicatricial formations in myocarditis (see Myocarditis). Finally, direct injuries to the heart, especially bullet-wounds, may also cause hæmorrhages into the pericardial sac.

In most cases death occurs in a few moments from compression of the heart, when a hæmo-pericardium comes on. Hence the amount of blood poured out into the pericardial sac is usually not very considerable. Only in the cases where the blood oozes out more slowly can a great distention of the pericardial sac be reached. The diagnosis is only rarely possible. With regard to treatment we can merely note that, in some traumatic cases, the aspiration of the blood has been performed with success.

### 3. Pneumo-Pericardium.

*(Air in the Pericardial Sac.)*

The entrance of air or gas into the pericardial sac has been observed in rare cases, apart from external wounds, as a result of the perforation of a pyo-pneumothorax, or of some other suppurating process in organs that contain air. Thus cases are known where the rupture into the pericardial sac comes from the œsophagus, as in cancer; from the stomach, in cancer or ulcer; or from the lungs, in tubercular or gangrenous cavities. Since the agents of inflammation enter the pericardium along with the air, a purulent pericarditis almost always develops, besides the pneumo-pericardium, or it may rarely be simply a sero-fibrinous pericarditis.

The most characteristic and striking sign of pneumo-pericardium is the presence of a metallic sound, due to the movements of the heart. Either the heart-sounds themselves, or some existing friction-rub, may acquire a metallic timbre from the increased resonance, or splashing metallic sounds may be produced in the pericardial sac from the movements of the air and the fluid, which may even be heard at a distance from the patient. In regard to diagnosis, however, it is important to know that signs similar to those of metallic resonance in the heart may arise from the stomach, when it is drawn or pushed upward.

In true pneumo-pericardium percussion gives a more or less complete absence of the cardiac dullness. On rod-percussion (see page 269) a metallic sound is some-

times heard, whose pitch may vary somewhat with the phase of the heart's action. If fluid is also present in the pericardial sac besides the air, the dullness caused by this will rise on raising up the patient.

The other symptoms of the disease and the treatment are the same as in a severe pericarditis. The prognosis, however, corresponding to the primary disease, is wholly unfavorable.

### SECTION III.

#### DISEASES OF THE VESSELS.

##### CHAPTER I.

#### ARTERIO-SCLEROSIS.

(*Endarteritis chronica deformans. Atheroma of the Vessels.*)

**Ætiology.**—Atheromatous degeneration of the arteries is chiefly a disease of advanced life, in persons over forty. It is often to be regarded, especially in old people, not as a disease, but as attributable to conditions of senile involution.

Besides age there are also a number of ætiological factors which favor an earlier occurrence and a greater extension of the atheroma. Among these are, first of all, chronic alcoholism; also syphilis, gout, chronic nephritis, articular rheumatism, and chronic lead-poisoning. It is, however, hard to find more positive evidence for the connection between atheroma and the conditions mentioned, although the special connection between alcoholism, and perhaps syphilis and arterio-sclerosis, is made probable by many observations. We must mention that in many families there is a pronounced hereditary tendency to atheroma of the vessels and its results. Men are decidedly more liable to the disease than women.

**Pathological Anatomy.**—Atheroma is almost exclusively confined to the arteries; only exceptionally do like processes occur in the veins. Among the arteries the aorta is almost always the most intensely and extensively diseased; we also find disease in the iliac and femoral arteries, the brachial, radial, and ulnar, the coronary arteries of the heart, and the arteries of the brain. In some of the other arteries, however, like the gastric artery, the hepatic, and the mesenteric, we very rarely find atheromatous changes.

The atheromatous process is easy to recognize macroscopically. Instead of the normal smooth internal surface, we find more or less numerous irregularities and thickenings on the intima, which appear either more or less gelatinous and translucent, or dense and fibrous, or ossified as a result of calcification, in which case they also feel perfectly hard. In extensive calcification the whole artery is changed to a hard, stiff tube. In many cases we find the surface of the thickenings destroyed—atheromatous ulcers—and covered with masses of thrombi.

Microscopic examination shows that the chief changes are situated in the intima of the arteries. This appears three or four times as thick as normal, partly from the swelling of its elements and partly from the new growth of connective tissue and the deposit of round cells. In the connective-tissue cells of the intima, and in the endothelial cells of its surface, we usually find a marked fatty degeneration, to which the yellowish, translucent appearance of the surface is due. Finally, in the deeper layers there is a complete breaking down of the tissue into

a mixture of fat, detritus, and cholesterine crystals, which has given the whole process the name of atheroma [= pulp]. If this destruction extends to the surface, an atheromatous ulcer is formed. In other places, however, it does not reach ulceration, but the superficial layers of the intima become sclerosed, and are finally changed to lamellæ of bony hardness from the deposition of lime-salts. The atheromatous spots on the intima of the vessels often give rise to the formation of parietal thrombi.

The media and adventitia of the arteries also show changes in the later stages of the process. Here, too, we may finally get fatty degeneration and calcification. In other cases, however, there is a marked atrophy of the media.

The immediate result of the atheromatous changes is a loss of elasticity in the walls of the vessels. The ability to resist the blood-pressure is reduced, and this is why diffuse or circumscribed aneurismal dilatations of the vessels so often arise as a result of arterio-sclerosis (see the following chapters).

Another result of extensive atheromatous degeneration of the vessels is an increase of the resistance to the blood-current, and a consequent elevation of the arterial pressure. Furthermore, the loss of elasticity in the coats of the medium-sized and smaller arteries removes an important factor for the propulsion of the blood. The left ventricle, in consequence of these additions to its task, becomes almost invariably hypertrophied in cases of extensive arterio-sclerosis, provided the general nutrition of the patient is still well maintained.

The thickening of the intima in the smaller vessels often causes so marked a diminution of the blood-supply that secondary disturbances of nutrition are not wanting in the various organs. The lumina of the vessels may be still further narrowed, or even completely closed, by the formation of thrombi on such portions of the wall of the vessels as have undergone atheromatous changes. We have already in part learned to recognize the sequelæ which necessarily arise in the various organs, such as indurations in the heart as a result of atheroma of the coronary arteries, and we will return later on to the analogous changes in some other organs, like cerebral softening and certain forms of contracted kidney.

**Clinical Symptom.**—In order to decide whether an arterio-sclerosis is present in the living subject, we are of course exclusively restricted to the examination of those peripheral arteries that are accessible to palpation. We must examine, first of all, the radial, brachial, femoral, and temporal arteries. If there is atheroma, we feel the hard and partly bony vessel-wall. In marked cases we have a feeling, especially in the radial, as if we had hold of a goose's neck. We sometimes notice a diffuse dilatation of the femoral arteries. In many cases the marked spiral form of the vessels is very striking, and it is a direct result of the loss of elasticity of their walls and of the increased blood-pressure. The spiral form is most frequently observed in the temporal, brachial, and radial arteries.

Although we can often directly demonstrate atheroma in the vessels mentioned, we must always be cautious in deciding from this that there is also an atheroma of the internal arteries, for the radial arteries often feel very rigid, while the autopsy later on shows little or absolutely no atheroma of the internal arteries. In other cases, however, we find at the autopsy marked atheromatous changes in the arteries of the brain, the kidneys, the heart, etc., although the external arteries during life felt perfectly normal. We see from this how hard it is to make an absolute diagnosis of general arterio-sclerosis.

It is impossible to give a uniform picture of arterio-sclerosis, since its results appear now chiefly in this organ and now chiefly in that, whereby entirely distinct types of disease arise. Hence we must confine ourselves here only to mentioning briefly the most important sequelæ. For the most part, they are described separately in other portions of this work.

In the heart we find a hypertrophy of the left ventricle as a result of the increased resistance to the arterial circulation. This is often apparent during life from the strength of the apex-beat and its displacement to the left, and also from the extension of the area of cardiac dullness to the left. On auscultation, the increased tension in the aortic system is made manifest by the strength of the aortic second sound. The examination of the heart, however, is often rendered difficult by the presence of pulmonary emphysema. On the other hand, we sometimes can not decide how far a manifest hypertrophy of the left ventricle is due to an arterio-sclerosis, and not to other co-existing processes, like contracted kidney. We often find other anatomical changes in the heart besides hypertrophy of the left ventricle. We have already spoken of the important and interesting results of atheroma of the coronary arteries, the formation of the so-called indurations of myocarditis in the heart (see page 308 *et seq.*). Sometimes, from an invasion of the aortic valves by the atheromatous process, we get an insufficiency, or much more rarely a stenosis of the aortic orifice. Finally, we may also mention here that atheroma, especially of the ascending aorta or the arch, is the commonest cause of the formation of aneurism of the aorta.

We have already described the character of the peripheral arteries. The radial pulse is hard and tense, and the wave is either quite large, or, where the tube is very narrow, small. Since the wall of the vessel contracts only slowly, in consequence of its loss of elasticity, the radial pulse is usually sluggish—*pulsus tardus*. This condition is also pronounced in the sphygmographic tracing, which shows a slow ascent, and a still slower descent, of the pulse-curve, and an absence of the elevation in the descending limb of the curve, due to the normal elasticity. The frequency of the pulse is quite different in different cases; it is often rather slow as a result of sclerosis of the coronary arteries (*q. v.*). The pulse is very often irregular as a consequence of changes in the heart. We sometimes find an abnormal delay in the radial pulse, or in the pulse in other arteries, in comparison with the heart-beat, from the lessened rapidity of transmission of the pulse-wave.

Besides the heart, the brain is the chief place in which we observe definite results of arterial sclerosis. The increased tendency to rupture which the atheromatous vessel-walls show, and the co-existing heightened blood-pressure, explain the comparatively frequent occurrence of cerebral hæmorrhages. Cerebral hæmorrhages very often (always, according to some authors) result from little miliary aneurisms, which have formed in the atheromatous cerebral arteries. Atheroma is also the most frequent cause for the formation of foci of softening in the brain, since the arterial changes may give rise to a closure of the cerebral arteries both from thrombosis and embolism. We will later describe in full the clinical symptoms of the affections mentioned.

In the kidneys, too, atrophic processes often develop from the diminution of the blood-supply owing to the narrowed lumina of the vessels, and they lead to a special form of contracted kidney. The origin of the granulated "senile kidney" is in large part due to atheroma of the renal arteries.

Gangrene of the extremities may arise from a plugging of their arteries by thrombosis, or more rarely by embolism. The so-called "senile gangrene" almost always depends upon arterio-sclerosis.

From all this it follows that the type of the disease may be very different in different cases. The symptoms in the vascular apparatus often predominate over all others. The heart, which is simply hypertrophied, or has undergone in part cicatricial degeneration, is finally paralyzed, and then all the symptoms of a chronic heart disease develop—dyspnoea, œdema, etc. If there is also albuminuria, a type of disease is produced which resembles that of contracted kidney. In other

cases, however, the symptoms in the brain are especially manifest, either alone or in combination with the other symptoms mentioned.

We must remark, however, in conclusion, that all the results of arterio-sclerosis mentioned may be absent for a long time or altogether. Many people have practically no symptoms at all from their arterio-sclerosis, and reach an advanced age, but we must always consider the possibility of the sudden occurrence of severe symptoms, and make our prognosis accordingly.

There is no question of a special treatment of arterio-sclerosis, since we are not in a position to affect the process by any remedy. In the individual case the treatment is directed according to the symptomatic indications resulting from the sequelæ. Prophylaxis, by avoiding the injurious influences mentioned as ætiological factors, is more important, as this may perhaps prevent, or at least delay, the development of the process.

## CHAPTER II.

### ANEURISM OF THE THORACIC AORTA.

**Ætiology and Pathological Anatomy.**—The circumscribed dilatation of an artery is termed an aneurism. The cause of its formation is almost always to be sought in a primary disease of the vessel-wall, which weakens its resistance to the blood-pressure. As we have already said in the previous chapter, it is chiefly arterio-sclerosis which lies at the foundation of aneurisms in many cases. The same factors, therefore, which favor the origin of arterio-sclerosis belong to the ætiology of aneurisms. It is also repeatedly asserted that severe physical exertion plays a part in the ætiology of aneurism of the aorta.

[The occurrence of aneurism in early middle rather than in advanced life shows that too much stress can be laid on atheroma as a cause. That sudden strain often plays an important part in the ætiology can scarcely be doubted, though the cases in which a perfectly healthy aorta yields locally to internal pressure must be very rare. It is highly probable that violent exertion tends to produce changes in the walls of the aorta. The far greater frequency of aneurism in the male sex is notable. Syphilis, gout, alcoholic excess, and lead-poisoning appear to be factors in some cases.]

The size of aneurisms of the aorta varies very much, of course, in different cases. They most frequently are about the size of an apple or the fist; but in rare cases much larger aneurisms are observed. According to their shape we distinguish the more diffuse or spindle-shaped dilatations from the saccular aneurisms (*aneurisma diffusum seu cylindricum*, *aneurisma fusiforme*, et *aneurisma saciforme*). Intermediate forms and combinations of the different forms occur in manifold ways.

As we should expect from its origin, we never find the wall of the aneurism formed of a normal vessel-wall. The intima almost always shows the same changes as are characteristic of arterio-sclerosis, only in a much higher degree. The media, too, is usually changed, and its muscular structure is often fatty-degenerated. The adventitia is usually thickened by chronic inflammatory processes. The media, and sometimes the intima, are in many cases so much atrophied that the wall of the aneurism, at least in part, is formed only of the adventitia.

In the cavity of the aneurism the blood is only partly fluid. We usually find it more or less full of new and old masses of thrombi. The oldest thrombi, which

lie upon the wall of the aneurism, are firm, yellowish, adherent to the wall, and sometimes calcified. At other points the thrombi are softened and broken down. The most marked coagulation is usually found in the saccular aneurisms with a narrow entrance, because in this form of aneurism the blood is almost completely stagnant in the aneurismal sac.

Aneurisms of the aorta usually have their seat in the ascending aorta, or in the arch. Aneurisms of the descending thoracic and of the abdominal aorta are far more rare. The following description refers principally to aneurisms at the beginning of the aorta. The other aneurisms will receive a brief separate description farther on.

**Clinical Symptoms.**—The subjective sensations of the patient, relating directly to the aneurism, are of a very uncertain nature, and are often entirely absent. In other cases there is pain in the region of the aneurism, either only a slight sense of pressure, or very severe and subject to paroxysmal increase. Sometimes, too, the patient feels the beating and pulsation of the aneurism. The remaining symptoms of aneurism may be divided into two groups. The first group embraces those symptoms which are directly related to the aneurism itself, and most prominent in this group are the physical signs. The second group of symptoms includes the resultant phenomena which the aneurism occasions in the circulatory apparatus and by pressure upon the neighboring parts.

1. *Physical Signs.*—It depends entirely upon the position of an aneurism of the aorta whether it causes physical signs or not. Deep aneurisms, which nowhere approach the chest-wall, may, of course, be quite inaccessible to direct examination.

Aneurisms of the ascending aorta, however, and of the arch, often extend so near to the anterior wall of the chest that they cause an abnormal pulsation. We feel this most frequently at the sternal end of the second right intercostal space, or over the upper part of the sternum. The pulsation of an aneurism of the arch of the aorta may sometimes be felt in the root of the neck. It often occurs a moment later than the systole of the heart. In many cases the pulsation is clearly double, analogous to the normal diastole of the pulse. We sometimes feel a slight systolic thrill with the flat of the hand. In the rare aneurism of the descending thoracic aorta the pulsating swelling may make its appearance in the back, between the vertebral column and the left scapula. If the aneurism has reached a certain size, the pulsating part protrudes as a tumor. The protrusion is either merely slight, or in many cases it forms a large prominent swelling. It then shows usually a marked pulsation, not only from below upward, but also in a lateral direction, which is of diagnostic significance. In large aneurisms, however, the pulsation sometimes is only very weak, and feels obscure, from the formation of many coagula.

The marked prominence of large aneurisms is possible only because the covering parts, not only the muscles and skin, but also the cartilages and bones, the ribs and sternum, are brought to a gradual atrophy and wasting by the persistent pressure. The skin over large aneurisms gradually becomes thinner and thinner, until finally it may even become necrotic.

In many cases percussion gives a positive result, since the resonance over the aneurism is necessarily more or less dull. The dullness is usually evident in the upper right intercostal spaces, or the adjacent parts of the sternum. Sometimes it even precedes the palpable pulsation, although then its significance is usually still very uncertain. In rare cases of aneurisms of the ascending aorta and of the arch, dullness and abnormal pulsation have been observed to the left of the sternum.

Auscultation gives varying results. In some cases (probably chiefly when

many coagula form) we hear nothing at all over the aneurism. In other cases we hear one or two sounds, which are usually the audible heart-sounds transmitted. Perhaps a systolic sound may also arise from vibration of the wall of the aneurism. In other cases, we hear a murmur over the aneurism. A dull and usually not very loud systolic murmur often arises from the formation of eddies in the aneurismal sac. If we also hear a diastolic murmur, it is almost always due to a co-existing insufficiency of the semi-lunar valves of the aorta (*vide supra*).

2. *Sequela*.—An aneurism of the aorta by itself probably never causes such an increased resistance to the blood-current as to give rise to the development of a hypertrophy of the left ventricle. In the quite frequent cases where hypertrophy of the left side of the heart exists, it may almost always be referred to a co-existing insufficiency of the aortic valves, and sometimes to very extensive atheroma of the arteries. During life a hypertrophy of the heart may be simulated, because the heart is pushed to the left by the aneurism.

In many cases the signs in the peripheral arteries are important. Marked inequality of the pulse in symmetrical arteries is often an especially valuable diagnostic sign. Either the trunk of an efferent vessel is compressed by the aneurism, or the lumen of the exit of the vessel is itself involved in the aneurism, and hence the opening of the vessel is distorted or contracted, or partly stopped by a coagulum. This readily explains why, in aneurism of the ascending aorta, the radial, and sometimes the carotid pulse, are plainly weaker on the right than on the left, as a result of implication of the trunk of the innominate, while in aneurism of the arch or of the beginning of the descending aorta the opposite condition may obtain. Abnormal differences, too, in the intensity of the pulse in the upper and lower halves of the body may arise under some circumstances.

[W. S. Oliver has described a valuable sign to which he gives the name of "tracheal tugging." In aneurism of the transverse arch with pressure on the left primary bronchus, a distinct downward pull, synchronous with the heart-beat, can be felt by the thumb and forefinger on either side of the inferior border of the cricoid cartilage, when the patient, in the erect or sitting posture and with the mouth shut, raises the chin as far as he can. The late R. L. MacDonnell, of Montreal, has shown that non-aneurismal tumors in this region are not accompanied by this sign, and that pressure on the trachea, from whatever cause, does not produce it. It may be the sole sign of aneurism present, and may then possess the double diagnostic value of indicating both the nature and exact seat of the disease.]

A marked delay of the pulse in the arteries arising below the aneurism is a symptom that is occasionally seen. Thus, we see in aneurism of the arch of the aorta that the left radial pulse is later than the right, and that in aneurism of the descending aorta the pulse in the lower extremities is later than the radial pulse.

We see very striking signs in the veins if the large venous trunks in the thorax, the superior vena cava, or an innominate vein, are compressed by the aneurism. The veins swell in the neck, in the upper extremities, or upon the surface of the thorax, according to the seat of the compression. Local cedema may also be produced in this way.

The respiratory organs are exposed to the pressure of aortic aneurisms in many ways. Compression of the lungs by large aneurisms actually contributes toward increasing the dyspnoea in many cases. This may be still more distressing if the trachea be compressed. Of the two main bronchi, the left bronchus, which lies beneath the arch of the aorta, is more apt to be compressed. This produces the symptoms of a unilateral bronchial stenosis (*vide supra*). The comparatively frequent compression of one recurrent nerve, especially the left, is also of diagnostic importance, as it results in paralysis of one vocal cord. We refer the occasional

paroxysms of severe dyspnoea to a compression of the branches of the vagus, but no *post-mortem* lesion has been found.

Very prominent symptoms sometimes arise from compression of the intercostal nerves or branches of the brachial plexus by the aneurism. As a result of this pressure, extremely severe and distressing neuralgias are felt in the nerve territories affected, and sometimes we see motor paresis in the arm.

Finally, disturbances of deglutition arise in many cases from compression of the oesophagus. If this be falsely interpreted, it may lead to a mischievous use of the oesophageal sound. Cases have repeatedly occurred where perforation of the aneurism has been caused by passing a sound into the oesophagus. Hence we must always remember this possibility in practice.

**Course and Termination of the Disease.**—Aneurisms may remain latent for a long time without causing any symptoms. In such cases a sudden perforation may lead to a speedy and unexpected death.

In the cases which have shown the above symptoms to a greater or less extent for a long time, and often for years, sudden death quite frequently results from rupture of the aneurismal sac and perforation into a neighboring organ. In perforation into the pericardium death follows almost instantly from cessation of the heart's action. In perforation into the oesophagus a fatal hæmorrhage occurs. In perforation of the aneurism into the air-passages, the trachea or bronchi, or into one pleural cavity, two factors, hæmorrhage and suffocation, unite in causing death. In aneurisms which gradually erode the anterior wall of the chest, the perforation is in rare cases external; but here a sudden, immediately fatal hæmorrhage rarely ensues; much more commonly a slowly increasing anemia develops as a result of repeated slight hæmorrhages which may sometimes go on for weeks. Death then is due to the gradually increasing weakness, or to a final severe hæmorrhage. Perforation of an aneurism into the right side of the heart, into the pulmonary arteries, or the vena cava, is a rare termination. Here death does not follow at once, but severe general disturbances of the circulation, like dropsy, soon arise. In many of these rare cases peculiar physical signs also appear—a venous pulse, a loud systolic murmur over the point of perforation, etc.

If, in patients with aneurism of the aorta, death does not ensue from a sudden perforation, the general type of the disease takes a form similar to chronic heart disease. The aneurism, as we have said, is often also combined with aortic insufficiency. The left ventricle gradually becomes paralyzed, and the well-known disturbances of compensation set in—increasing dyspnoea, œdema, etc. In other cases the patient gradually becomes duller and weaker from the distressing pain, the sleeplessness, and the other symptoms, and dies with the signs of increasing general weakness.

Recovery from aneurism of the aorta scarcely ever occurs.

**Diagnosis.**—The diagnosis of aneurism of the aorta can in many cases be made with great ease and certainty, but in other cases it is very difficult and even impossible. If the direct physical signs are plain, especially if we feel an abnormal pulsation, we shall not be apt to commit an error; but the diagnosis presents great difficulties in those cases where the aneurism is not accessible at all, or accessible only with great difficulty, where it merely causes indefinite symptoms, pain in the chest, occasional oppression, symptoms of pressure on neighboring organs, etc. A very stubborn intercostal neuralgia, which no remedy can relieve, may be for a long time the only symptom, often misinterpreted, of a latent aneurism. The disease is often not recognized, however, because in such cases we do not generally think of the possibility of an aneurism, and hence we neglect a careful examination of the heart and the arteries, and also the search for other symptoms of compression, like paralysis of the vocal cords; but sometimes, even with the

most careful examination, the diagnosis can not amount to more than a suspicion.

The distinction between aneurism and other tumors in and about the thorax sometimes presents difficulties in diagnosis. Mediastinal sarcomata and abscesses, circumscribed empyemas, tumors arising from the sternum, or new growths in the lungs and bronchial glands, may all give rise to confusion. We can scarcely lay down any general rules for diagnosis, since the conditions differ in almost every case. If we feel a swelling, its pulsation is the symptom which points most to an aneurism, but we must be certain that the pulsation is not merely transmitted, but that it really takes place in all directions within the swelling itself. We must also consider the auscultatory symptoms, the condition of the heart and the arteries, and also any symptoms of compression; yet in such cases we can not always make a definite diagnosis.

**Treatment.**—Many attempts have been made to bring about an obliteration of the aneurism, and thus a recovery. Although the methods of treatment aiming at this have obtained decisive results in the aneurisms of peripheral arteries, their results in aneurism of the aorta are still of a very doubtful character; yet we are always justified in any given case in trying one of the methods recommended.

Persistent compression by a pad can of course be employed only in those cases where the aneurism projects at one part of the chest-wall. The pressure, however, usually causes great pain, and hence is ill borne.

Tying the carotid, the subclavian, or both vessels, has also been repeatedly performed in aneurism of the arch of the aorta, sometimes with apparent success, but oftener without any benefit.

"Acupuncture" of the aneurism (Velpeau) consists in inserting a needle or an iron wire into the aneurismal sac in order to excite coagulation in it. The results obtained by it in aneurism of the aorta are not very encouraging.

Better results are reported from galvano-puncture. Two needles inserted into the aneurism are connected with the poles of a galvanic battery, by which a weak current is passed through the aneurism. Here we must regard the chemical and electrolytic action of the current as well as the mechanical action of the needles.

Injections of chemical substances into the aneurismal sac, in order to produce coagulation, are dangerous, since the coagula caused by them may give rise to emboli. Hence we have abandoned making trial of liquor ferri sesquichloridi and similar substances. We can better recommend injections of ergotine into the vicinity of the sac, two to five grains (grm. 0.1-0.3) of the aqueous extract of ergot dissolved in water or glycerine, injected every day or two. This method was first employed with success by Langenbeck in peripheral aneurisms. Its action depends upon a contraction of the smooth muscles in the wall of the aneurism, caused by the ergotine.

We can expect little action on an aneurism from the use of internal remedies, although favorable results have been repeatedly reported. Acetate of lead, five to ten grains (grm. 0.3-0.6) a day, and iodide of potassium, half a drachm to a drachm (grm. 2-4) a day, are most praised.

The symptomatic treatment of aneurism, which tries to relieve the patient's sufferings, and the dietetic measures prescribed, follow the generally customary principles. In a rupture of the aneurism externally we try to avert the fatal catastrophe by absolute rest, ice-bags, styptic cotton, etc. Treatment is powerless against internal perforations.

[Tufnell's method, so-called, which has given good results in abdominal and peripheral aneurisms, proves sometimes useful in palliating the symptoms and lengthening the course of aortic aneurism. The aim of this method is to diminish

the force and rapidity of the circulation, and, if possible, to increase the fibrinous deposit. It is carried out by enforcing absolute rest in the recumbent position, and by limiting the amount of food, especially of liquids. About ten ounces of solid food and eight of liquid are allowed daily, divided into three meals.]

### CHAPTER III.

#### ANEURISMS OF THE OTHER VESSELS.

*Aneurism of the Abdominal Aorta.*—Its favorite seat is the vicinity of the coeliac axis. In many cases it may be felt through the abdominal wall as a pulsating tumor, over which a systolic sound or a whirring murmur can be heard. The possible symptoms of compression are very numerous. The stomach, intestine, and liver (jaundice) may be implicated. Pressure of the aneurism upon the nerve trunks, or even pressure on the spinal cord after gradual erosion of the vertebrae, with consequent severe neuralgia, paralysis, etc., has been repeatedly observed. Death usually ensues from rupture of the aneurismal sac and internal hæmorrhage.

Aneurism of the trunk of the innominate is rare. Its symptoms are very much like those of an aneurism of the arch of the aorta. If we feel a pulsating tumor, it is usually situated somewhat higher up than the aneurism of the aorta, in the first right intercostal space, or the tumor even extends into the supraclavicular fossa. In rare cases aneurisms of the subclavian and of the carotid have been observed. We have ourselves seen an aneurism of the internal carotid the size of a cherry pressing on the Gasserian ganglion, which caused an extremely severe trigeminal neuralgia lasting for years.

Aneurism of the pulmonary artery may appear as a pulsating tumor in the second left intercostal space. It is usually impossible to distinguish it with certainty from an aneurism of the aorta.

We have already mentioned, in the description of pulmonary tuberculosis, the great importance of small aneurisms of the branches of the pulmonary artery in pulmonary cavities, as a frequent cause of hæmorrhage.

Aneurisms of the arteries of the brain, which are relatively most frequent in the basilar artery and the artery of the fissure of Sylvius (the middle cerebral artery), may cause severe cerebral and bulbar symptoms (see page 693). As has already been mentioned, miliary aneurisms of the cerebral arteries play an important part in the ætiology of cerebral hæmorrhage (*q. v.*).

The symptomatology and treatment of aneurisms of the peripheral arteries belong to the domain of surgery.

### CHAPTER IV.

#### RUPTURE OF THE AORTA.

A RUPTURE of a previously healthy aorta, with fatal hæmorrhage, after violent traumatic influences, has been seen only in a very few cases. In the majority of the very rare cases of rupture of the aorta we have to do with a vessel that is already atheromatous. In some cases a special exciting cause is present, and in others it is absent. We once saw sudden death caused by rupture of the ascending aorta in a young man about twenty-five, who before that seemed perfectly

healthy. No trace of atheroma was found; but at the point of rupture there was a slight protrusion and a decided thinning of the wall, which was probably congenital. The formation of a so-called dissecting aneurism, which has often been seen in the aorta, is of anatomical interest. Here only the intima and media are torn. The blood burrows between them and the adventitia or between the layers of the media. Most of the cases of dissecting aneurism of the aorta also result, like rupture of the aorta, in sudden death. In many cases death results from the secondary perforation of the aneurism into the pericardium. On the other hand, a sort of recovery from dissecting aneurism may occur. A secondary perforation takes place into another part of the aorta itself (Boström). Cases of this sort were formerly more than once mistaken for double aorta. If the capsule containing the blood is preserved for a considerable length of time, the symptoms may assume the character presented in ordinary aortic aneurism.

## CHAPTER V.

### NARROWING OF THE AORTA.

CONGENITAL narrowness of the aorta and its branches is a condition to which Bokitsky first, and later Virchow, have directed attention. We find this anomaly especially in those, mostly women, who during life have shown the signs of persistent chlorosis. Sometimes such persons are backward in their whole development; they retain a puerile habit, and show a defective development of the genitals. They often suffer from palpitation, faintness, and a tendency to hæmorrhagia. In many cases the heart is also small, but in others it is dilated and hypertrophied. Valvular disease of the heart has been repeatedly found combined with general narrowness of the arterial system. During life this anomaly of the vascular system may sometimes be suspected, but it can never be recognized with certainty.

Narrowing of the aorta at the point of insertion of the ductus arteriosus is a lesion observed in rare cases, whose origin probably always falls in the period directly after birth, and is associated with obliteration of the foetal ductus arteriosus. Other congenital anomalies of the heart are usually present at the same time. If the narrowing of the aorta is not very marked, it may be properly equalized by a secondary hypertrophy of the left ventricle and the development of a collateral circulation. The latter is brought about by dilatation of the anastomoses between the first intercostal artery, the dorsalis scapulae, the subscapularis, and the transversalis colli on one side, and the lower intercostal arteries, which come off from the descending aorta below the narrowing, on the other. Anastomoses are also formed between the mammary and the superior epigastric on one side and the lumbar and femoral arteries on the other. During life the dilated arteries are prominent, in part abnormally distorted, and perceptibly pulsating, especially the dorsales scapulae, the subscapulars, the mammaries, and the epigastrics. In some cases a systolic murmur has been heard over some of these vessels. The pulse in the arteries of the lower extremities, the femoral and popliteal, is very weak and scarcely perceptible.

In many cases the collateral circulation is so complete that the person affected may feel no subjective disturbance at all, and may attain an advanced age, but in other cases disturbances of the circulation appear sooner or later, and the patient finally succumbs to dropsy. Sudden death from rupture of the heart or of the aorta has also been observed.

# DISEASES OF THE DIGESTIVE ORGANS.

---

## SECTION I.

### *DISEASES OF THE MOUTH, TONGUE, AND SALIVARY GLANDS.*

#### CHAPTER I.

#### **STOMATITIS.**

*(Inflammation of the Mouth.)*

**Ætiology.**—Inflammation of the buccal mucous membrane is not infrequently the direct result of mechanical or chemical causes. As mechanical causes we may mention particularly the sharp edges of broken or carious teeth. Chemical irritation may come from highly spiced food, or from tobacco-chewing or excessive smoking. Very intense inflammation is caused by acids, alkalies, and the like, attacking the mucous membrane. Mercurial stomatitis is also of practical importance. It is caused by mercurial poisoning, or not infrequently by the therapeutic employment of the drug. The stomatitis attendant upon the cutting of teeth in children will be discussed below.

In many instances stomatitis comes from a direct propagation of inflammation from neighboring parts. It thus forms a frequent complication of pharyngeal catarrh, and less often of rhinitis.

Infection plays an important part in the ætiology of stomatitis. The local inflammation may be merely part of a constitutional infectious disease, as in measles, variola, and syphilis. Stomatitis is still more frequently a complication of some severe and protracted illness, where the mouth is not properly attended to and cleansed. The bits of food and the mucus quickly begin to decay. Great numbers of fungi and bacteria invade the buccal cavity, and excite inflammation in its mucous membrane.

Scorbutic stomatitis will be considered under scurvy.

**Clinical History.**—The usual symptoms of an inflammation of mucous membrane—namely, redness, swelling, and increased secretion—are exhibited in stomatitis. The redness is usually most intense on the inside of the cheeks and on the gums. Indeed, we have the special name—gingivitis—for inflammation of the latter. The swelling is best shown by the indentations made by the teeth in the cheeks and the edges of the tongue. The tongue and gums are smeared with mucus. There is often considerable salivation. If the inflammation is more active, we find a purulent coating on a greater or less portion of the membrane. The tongue is almost always thickly coated. If we scrape off a little of the coating and put it under the microscope, we find a great abundance of pavement epithelium, in part fatty-degenerated, pus, micrococci, bacilli, occasionally mold-fungi, and remains of food. White spots made up of epithelium may also be formed elsewhere than on the tongue. Here and there little vesicles appear which burst and leave superficial ulcers.

The local discomfort of severe stomatitis is by no means trifling. There is burning pain, which interferes with taking food, and usually the processes of decomposition occasion a constant bitter or disgusting taste in the mouth, as well as a foul and offensive breath.

The duration of the disease depends on the nature of the immediate cause or the character of the primary disorder. Usually a stomatitis which gets well in one or two weeks is called acute, and a more tedious attack, chronic. The chronic form is seen in toppers and inveterate smokers. It may last for years, with the symptoms described above, only milder. (For lingual psoriasis, *vide infra*).

**Treatment.**—If the inflammation is considerable, the diet must be liquid. Sometimes cold drinks are most agreeable, sometimes lukewarm. Often the pain is relieved by taking from time to time a sip of iced water or a bit of ice; but it may happen that the patient will prefer to rinse the mouth with lukewarm water. The important indication, to keep the mouth as clean and pure as possible, is best met by having the mouth frequently rinsed out with a one- or two-per-cent. solution of carbolic acid, a two-per-cent. solution of chlorate of potash, or one or two teaspoonfuls of a one-per-cent. solution of permanganate of potash to a glass of water. In children who can not do this, the mouth is to be carefully washed or sprayed. If the gums are spongy, they should be painted with a mixture containing equal parts of tincture of myrrh and tincture of rhatany. If there are superficial ulcers scattered about, it is sometimes an excellent plan to touch them lightly with lunar caustic, to hasten their healing.

Chronic stomatitis is often very obstinate, resisting all sorts of treatment for a long time. The first thing is to remove any such injurious agencies as tobacco or bad teeth. It is recommended to swab out the mouth with a solution of corrosive sublimate (1 to 5,000) or of lunar caustic (1 to 30-50). A well-known household prescription is to chew bits of rhubarb.

---

## CHAPTER II.

### ULCERATIVE STOMATITIS.

(*Stomatocae.*)

**Ætiology.**—By ulcerative stomatitis is meant a severe disease of the buccal mucous membrane, with superficial necrosis and the consequent formation of ulcers. The abnormal processes are not in all cases identical, and their cause may vary. Still it is probable that infection is the important factor, at least in most cases. The disease has repeatedly been epidemic, chiefly among soldiers in barracks or on a campaign, and among the inmates of jails. It also occurs in children, principally at the time of the second dentition; and in such cases, also, the evidence of contagion and of endemic influences is often very striking. Mercurial stomatitis, if severe, always assumes the form of ulcerative stomatitis. (For the scorbutic form, see page 959.)

**Symptoms.**—The disease usually attacks the gums of the lower jaw first, gradually spreading thence to neighboring portions of the lips and cheeks. The tongue and palate are generally not very much affected, though often the seat of a simple catarrhal inflammation.

Inspection shows that the mucous membrane in the places mentioned has a thick, soft, purulent coating. The gums are swollen, spongy, and red, and bleed easily. In severe cases the incisors become loose, and may fall out. There is usually profuse salivation. The lymph-glands at the angle of the lower jaw and

on the chin are generally swollen. The breath is very offensive, poisoning the air of the whole room.

The local discomfort of the patient is the same as in simple stomatitis, only much worse. It is very difficult to take nourishment. In many cases there are marked constitutional symptoms. The patient feels very weak and languid. There may be moderate elevations of temperature, particularly in children. Now and then severe symptoms of constitutional sepsis have followed the disease.

The course of ulcerative stomatitis is favorable in the great majority of cases. With good treatment and nursing, the ulcers gradually clean up, and at the end of one or two weeks recovery is complete. Exceptionally, the disease may be more chronic. The most frequent way in which recovery is delayed is that the disease extends to the periosteum of the lower jaw, causing necrosis of small portions of the bone, which must be expelled before the patient gets well.

The **treatment** does not differ essentially from that of the milder forms of stomatitis. The mouth must be still more carefully and more frequently cleansed and disinfected. A solution of potassic chlorate (1 to 30) is the favorite mouthwash. Some authors strongly recommend the simultaneous internal administration of this remedy; but we must employ it cautiously in children, as it has repeatedly caused poisoning. For children two or three years old we ought not to give over fifteen to thirty grains (grm. 1-2) in a day.

As to prophylaxis, we should mention that all patients who are using mercury should employ a gargle of potassic chlorate faithfully from the beginning of treatment, in order to prevent the occurrence of mercurial stomatitis. If salivation occurs, the mercury must be stopped.

### CHAPTER III.

#### APHTHÆ.

(*Aphthous Stomatitis.*)

APHTHÆ is a name given by physicians to several entirely distinct diseases. Many doctors call every disease aphthæ in which there are white spots upon the buccal mucous membrane. It is thus frequently confounded with thrush. German mothers often apply the same name (*Schwämmchen*, or fungus) indifferently to thrush and to aphthæ.

There is a special form, known as Bednar's aphthæ. In new-born children white patches are not infrequently found lying symmetrically on both halves of the hard palate near the alveolar processes, and persisting till about the third month. These plaques are not syphilitic, although often thought to be. They are probably merely due to the tongue pressing upon the thin mucous membrane during nursing. Generally they do no harm; but in marantic, ill-cared-for children, they may develop into quite deep ulcers. In that case, repeated cauterization with a five-per-cent. solution of argentic nitrate is required.

The genuine aphthæ are roundish spots upon the mucous membrane, grayish white, and of small size, unless made larger by the confluence of several into one another. They usually have a narrow, red areola. They are most numerous on the edges and dorsum of the tongue and on the frænum, but they also occur on the lips and cheeks. The attempt to remove the white spot with forceps never succeeds, but does cause bleeding. In addition to the genuine aphthæ there are almost always the signs of a common stomatitis, which may be mild or severe. The white spots are in part due to a thickening and opacity of the epithelium, and

in part are said to be caused by the formation of a fibrinous exudation, which penetrates the most superficial layers of the mucous membrane.

The disease occurs chiefly in children, and at the time of the first dentition. The child is usually restless, often somewhat feverish, and evidently suffers pain when nursing. Generally there is considerable salivation. The lymph-glands may be a little enlarged. Herpetiform vesicles may appear on the lips. The disease is not rare in adults. Many individuals seem especially liable to it, and very frequently have little, white, and often very painful spots here and there on the tongue or elsewhere in the mouth. These have a tendency to develop into superficial ulcers. They may prove very troublesome, from their frequent recurrence and the hindrance they cause to speaking and mastication.

The prognosis, except as just described, is always favorable. There is usually complete recovery in a week or two. The treatment of children consists in carefully washing out the mouth with cold water, and in administering potassic chlorate. Of a mixture consisting of three parts of potassic chlorate, twenty of syrup, and a hundred of water, we may give a dessertspoonful every two hours. If the spots do not disappear, we can paint them with a five-per-cent. solution of sulphate of zinc, or a solution of borax (1 to 30). If some of the places are especially painful, particularly in adults, we may touch them with lunar caustic, when they usually are soon cured. In the constantly recurring form, treatment sometimes proves almost unavailing. Local cauterization, which unfortunately in such cases is often of no benefit whatever, and the use of a mouth-wash containing chlorate of potash or carbolic acid in weak solution, may be employed, and, furthermore, some physicians strongly recommend the internal administration of iodide of potash. Calomel also appears sometimes to have a beneficial influence.

In conclusion, as to aetiology, infection is a not unlikely cause, if we consider that small epidemics or endemics have repeatedly occurred. Lately attention has been called to the possibility that the milk of cows suffering from hoof-and-mouth disease may be a source of infection. That this may happen seems indubitable; but how frequently it occurs, future observations must determine. The cause of the above-described chronic form is unknown.

## CHAPTER IV.

### THRUSH.

(*Soor. Muquet.*)

**Ætiology.**—Weak and artificially nourished children are particularly liable to this disease; but it also attacks adults who are suffering from phthisis, carcinoma, and severe typhoid or typhus fever. In it, grayish-white deposits are developed upon the buccal and pharyngeal mucous membrane. The microscope shows these collections to be fungi; there are a multitude of oval spores, or conidia, and a tangled mass of long mycelium threads. Until lately the fungus of thrush was called *oidium albicans*, and was held to be identical with the *oidium lactis* found in sour milk. A more recent investigation of Grawitz has rendered it very probable, however, that the thrush fungus is a budding fungus, and is closely related to the comb fungi (*mycoderma vini*,\* or *saccharomyces albicans*, according to Rees). It seems to be a sort of transition form between the budding fungi and

\* *Mycoderma vini* is a fungus which is found associated with the formation of acetic acid out of alcohol, that is, when alcoholic beverages "sour."

the thread fungi, inasmuch as it appears both in a form resembling yeast and also in the form of long thread-like mycelia. At any rate, the thrush fungus is widely distributed, for the development of thrush upon the mucous membrane of the mouth and throat is a frequent phenomenon. Nursing-bottles and the nipples used upon them are probably not infrequently the agents by which the disease is conveyed.

**Symptoms.**—The mucous membrane of the tongue, cheeks, and soft palate is usually somewhat red and swollen. Upon it we see at first small white spots, which may gradually spread. Microscopic investigations have shown that the fungus develops first in the middle layers of the epithelium. From this starting-point it grows not only upward, but also downward into the mucous membrane. If the growth is abundant, it is easy to scrape off the upper layers, and make a diagnosis by aid of the microscope. In exaggerated cases the growth may even extend from the pharynx into the upper part of the œsophagus and the entrance of the larynx. But we never find thrush in the larynx itself, or the nostrils, or the stomach—briefly, in no place where there is cylindrical epithelium.

As a rule, thrush is accompanied by a more or less severe stomatitis. The fluids of the mouth have an acid reaction. Nursing, or chewing, and swallowing, are painful. Still, it is a question whether the stomatitis is due to the fungus, or whether it prepares the territory for the fungus to settle in. Nursing infants, who suffer from thrush, often have diarrhœa or marasmus at the same time, which latter affections are more probably the cause than the result of the thrush. If vigorous and healthy sucklings are attacked by thrush, the disease is usually quite harmless, quickly vanishing if proper cleanliness is maintained. In sickly children, particularly if bottle-fed, the appearance of the disease is very ominous. In adults, thrush is seldom seen except when there is great general prostration; and it is therefore, to a certain extent, an unfavorable symptom.

**Treatment.**—To prevent the development of thrush in children, the mouth must, if possible, be wiped out, each time they drink, with a cloth wet in cold water; and if adults are very ill, they require equal attention in this regard. As soon as we see the first traces of the disease, we should touch the parts attacked with a brush wet in aqueous solution of borax (1 to 30) or of sodic carbonate (1 to 20). Honey should not be added to the borax solution, as is often unwisely done. If the thrush has once got a vigorous start in the mouth of marantic children, or of adults suffering from an incurable disease, it must be confessed that we often fail to check its growth.

## CHAPTER V.

### GLOSSITIS.

(*Parenchymatous Inflammation of the Tongue.*)

INFLAMMATION of the true lingual parenchyma is rare, although the tongue's mucous surface is frequently involved in the various diseases of the mouth.

1. **Acute parenchymatous glossitis** is the name given to an inflammatory infiltration of the whole or a part of the tongue, usually ending in abscess. The most frequent cause is the sting of a bee or wasp, or it may follow burns or severe cauterization. In the rare instances where it is apparently spontaneous, it is probable that some little wound has afforded ingress to the inflammatory poison.

The symptoms of acute glossitis are very violent in the severer cases. The tongue is enormously swollen, so as sometimes to protrude from the mouth. It has a thick, soft, purulent coating, and often presents excoriations and ulcerations.

The subjective symptoms are very disagreeable. The patient has violent pain. Talking and eating are almost impossible. There is usually catarrhal inflammation of the rest of the mouth. The cervical lymphatic glands are swollen. The salivation is profuse and very annoying. In many cases the tongue swells so much as to cause dyspnoea and more or less suffocation. There is usually fever.

Treatment consists in the employment of ice, which the patient should keep constantly in his mouth, if possible. Very great relief follows deep scarification done in a few places where the swelling is greatest. As soon as fluctuation is obtained, we must give exit to the pus. This is usually followed by a rapid abatement of the discomfort, and complete recovery. It is the exception that the increasing dyspnoea necessitates tracheotomy.

**2. Glossitis Dissecans.**—This is a chronic disease, of rare occurrence and unknown ætiology. It causes the gradual development upon the surface of the tongue of a number of deep fissures and indentations, giving the organ an uneven and ragged look. The pain is due to the frequent presence of excoriations and ulcers in these fissures.

The trouble is not intrinsically dangerous, nor does it need special treatment. We should prescribe cleanliness and the use of some disinfectant mouth-wash. Ulcers, if present, must be touched with lunar caustic.

**3. Lingual Psoriasis. Leucoplacia.** (*Tylosis; Ichthyosis linguae et oris.*)—This, again, is a superficial disease, the ætiology of which is unknown. It consists in localized hyperplasia of the epithelium of the tongue, sometimes conjoined with similar spots upon the cheeks and lips. Usually the tongue gets to look like a map ("*lingua geographica*"). The disease generally lasts years, but causes discomfort only when extraordinarily severe. Still, it may cause a hypochondriac endless anxiety, especially if he takes it to be syphilitic.

This last statement applies still better to a peculiar disease allied to psoriasis. It is called leucoplacia, and affects the mucous membrane of the tongue and mouth. Usually it causes the appearance, on the lateral borders of the tongue, of dull-whitish spots, which have the look of scars, and are generally somewhat notched. As a rule, the cheeks display at the same time similar white spots, which are evidently due merely to thickening of the epithelium. Certain spots may disappear, but are sure to be replaced by others, so that, as far as has yet been observed, the disease must be regarded as incurable. Still, it is not of great importance, for in many cases the local discomfort is very slight. If the indentations along the sides of the tongue become cracked or ulcerated, then there may be great pain. The cause of leucoplacia is not yet known. It certainly is not syphilitic, although the disease is said to be especially prone to attack those who have at some former time been infected with syphilis. This does not apply to all cases. Nor is excessive smoking connected with the disease; we have seen leucoplacia in women. Treatment is, as we have said, usually unsuccessful. Still, thorough cleanliness and good care of the mouth may avert any great discomfort. We may try the effect of painting the spots with a five-per-cent. solution of chromic acid. The chief importance of knowing the disease is to prevent our confounding it with syphilitic affections, and thus to save the patient groundless apprehension and needless mercurialization.

## CHAPTER VI.

## NOMA.

(*Water-cancer. Cancrum oris.*)

NOMA is a gangrene of the cheek, apparently of spontaneous origin, and attacking chiefly feeble and sickly children. The disease is rare. It may be primary, but is usually a sequel of severe diseases, like measles, scarlet fever, typhus and typhoid fevers, and pneumonia. Now and then it has been observed in adults. *A priori*, it is extremely probable that noma is due to some parasitic micro-organism; but the matter has not yet been minutely investigated. It deserves mention that noma is said to occur with much greater relative frequency in moist regions along the coast—for example, in Holland—than among us in Germany.

The disease begins, without any evident occasion, in an insignificant spot of gangrene on the inner surface of the cheek—that is, in the mucous membrane. It is usually situated near the corner of the mouth. Externally, the parts are soon swollen by collateral œdema, and the whole cheek gradually becomes hard and infiltrated. At first, all we see upon the mucous membrane is a dirty-greenish spot not much larger than a silver dime, but soon the whole cheek and the neighboring parts are one mass of gangrene. Bits of dead tissue come away, and foul-smelling ichor flows continuously into the mouth. The collateral œdema may finally pervade that entire half of the face. The neighboring lymph-glands are always greatly swollen.

This condition is almost always accompanied by fever, often reaching or exceeding  $104^{\circ}$  ( $40^{\circ}$  C.). The general health may indeed for a time be astonishingly little affected; but gradually prostration comes on, or even general sepsis develops, with fever, stupor, and delirium. Frequently lobular pneumonia, which may have a gangrenous character, is produced by the inhalation of sloughing bits of tissue; and often the ichor, being swallowed, excites violent and offensive diarrhœa. The local discomfort is not really very considerable in most cases, compared to the severity of the disease. There may even be no pain felt whatever.

The prognosis is almost always fatal. Death sometimes occurs suddenly from collapse. Sometimes it comes at the end of three or four weeks, from a gradual sinking of the bodily powers. Recovery has been seen in only a few cases; there is a line of demarkation formed, the sloughs come away, and a slow convalescence follows, leaving extensive and usually very disfiguring scars behind.

Treatment must have for its chief object to check further extension of the gangrene, by removing all parts that are already destroyed. Local cauterization with concentrated hydrochloric acid, or fuming nitric acid, or lunar caustic, or chloride of iron, is usually futile. It is probably the best way to remove all the gangrenous portion by means of Paquelin's thermo-cautery. At least in the early stages of noma we may hope something from this method of treatment; but if the case is far advanced, we can hardly expect to accomplish much.

We should also disinfect the mouth as thoroughly as possible. The most efficient means is to syringe it out with solutions of salicylic or carbolic acids, or permanganate of potash, and to dust it with iodoform. We should do our best to maintain the patient's strength.

---

## CHAPTER VII.

## PAROTITIS.

*(Mumps).*

PAROTITIS, or inflammation of the parotid gland, appears not only as a peculiar, primary, infectious disease, usually epidemic, but also as a secondary complication of numerous other severe diseases. These two forms should be considered separately.

**1. Idiopathic, Primary Parotitis** (*Epidemic Mumps*).

**Ætiology.**—The disease occurs in epidemics that, although not very frequent, may be quite extensive. Here and there a sporadic case is seen. Children and young adults are most liable to it. Nursing infants enjoy a marked immunity, as well as elderly persons. Males are much oftener attacked than females.

There can be no doubt that mumps is a specific infectious disease; but we possess no minute knowledge of the infectious agent. Still, it is natural to suppose that the infectious matter reaches the gland by way of Steno's duct.

Numerous observations support the view that the disease is directly contagious. The period of incubation seems to vary. On the average, it is about fourteen days.

**Clinical History.**—There may be a prodromal stage of one or two days, with mild feverish symptoms. The disease itself begins with swelling of one parotid gland. The swelling is directly below and in front of the lobe of the ear, which is gradually pushed upward. In the next few days the swelling rapidly increases, and it and the collateral oedema of the cheek and floor of the mouth may become very considerable. The face is much distorted, but often makes a very comical impression, especially as everybody knows how harmless the disease is. In most cases the other gland also swells a few days later.

An abscess hardly ever forms in genuine mumps, nor does the swelling often become very hard. Generally it has a somewhat doughy consistence. The corresponding portion of skin is usually pale and shiny. The submaxillary gland not infrequently swells also in addition to the parotid, and this may occur upon one or both sides of the neck. Penzoldt has observed cases where the submaxillary and sublingual were swollen, but not the parotid. We ourselves have seen a swelling of the submaxillary precede the parotitis.

The local discomfort is moderate in most cases. There is difficulty in chewing, swallowing, and talking. Often quite a severe stomatitis develops, with foul breath.

There often seems to be no fever whatever. Sometimes there may be a moderate elevation of temperature, seldom exceeding  $102.5^{\circ}$  ( $39^{\circ}$  C.). Only occasionally has there been a case with grave typhoidal symptoms.

**Complications.**—It is not rare for men to have a swollen testicle, which may be quite painful, but usually subsides in a few days. Resultant suppuration is a rare occurrence. Double orchitis is rare. In boys this complication is much more exceptional than in adults. Some observers have mentioned analogous swellings of the female genitals and mammae, but this is doubtful.

The prognosis of epidemic parotitis is, as we have said, almost always favorable. The trouble seldom lasts more than a week or ten days, when the swelling goes down, and the patient completely recovers.

The diagnosis is easy. The only thing to exclude is swelling of the lymph-glands, and they never have exactly the same location as the parotid.

Special treatment is hardly necessary. Children should be kept in bed.

Usually some salve, like vaseline, is applied to lessen the feeling of tension. If resolution is tedious, we may paint the swelling with iodoform collodion (1-15) or with tincture of iodine; or we may prescribe iodoform ointment (1-15). If there is orchitis, the testicle must be elevated, as by a suspensory bandage. If the pain and swelling are marked, an ice-bag should be applied.

2. **Secondary Parotitis**, or "*Metastatic Parotitis*."—This secondary form may be a complication of any grave disease. In most cases it is due to inflammatory agents generated by decomposition of matters in the mouth, which agents reach the gland through Steno's duct. It was formerly the universal belief that the infection was metastatic, being conveyed through the blood-vessels; but it is doubtful whether this does occur. It is probable that the pyæmic form is in many instances thus produced. Secondary parotitis is most frequently observed in typhus and typhoid fevers. It is also seen occasionally in all other severe acute diseases, and in phthisis and carcinoma.

The parotid gland swells, just as in the primary disease. It is, however, much oftener of excessive size, and in the majority of cases suppurates. If one has an opportunity to make an autopsy on such a case of secondary parotitis in its early stages, the cross-section of the swollen gland presents a large number of rather small discrete abscesses. These finally unite to form one larger abscess, which usually discharges outward, or into the external auditory meatus. Sometimes the parotid suffers from gangrenous inflammation, and there is extensive sloughing. If such a case finally gets well, still, as a rule, some permanent injuries have been inflicted: there is facial paralysis, due to destruction of the facial nerve, or deafness, caused by an extension of the inflammation to the middle ear.

The treatment of secondary parotitis is that of any phlegmonous inflammation. We may at first try to scatter the swelling by ice or iodoform ointment, but this usually fails. As soon as fluctuation is detected, the spot must be incised, and a drainage-tube inserted. The prognosis depends chiefly on the nature and course of the original disease.

## CHAPTER VIII.

### ANGINA LUDOVICI.

THE name *angina Ludovici* is applied to a rather rare phlegmonous inflammation of the floor of the mouth. Its starting place seems to be the submaxillary gland, at least in most cases. It may be primary, or a complication of other severe acute diseases.

Angina Ludovici usually begins with swelling in the neighborhood of the submaxillary gland. The swelling rapidly increases, and comes to involve the whole floor of the mouth and the anterior surface of the throat. It causes great discomfort. Talking, chewing, and swallowing are almost impossible. There is usually fever, and in many cases we even find the symptoms of general sepsis. There may be great dyspnoea, due either to compression of the larynx or to œdema of the glottis. The final result in some cases is an extensive sloughing of the soft parts. This has the special name of *cynanche gangrenosa*. In other cases an abscess forms, and points outward or into the oral cavity. The swelling is sometimes, though seldom, reabsorbed.

The prognosis should always be guarded, for severe constitutional symptoms and a fatal ending are not infrequently seen, particularly if the patient has a weakly constitution. There may also be repeated exacerbations and relapses.

*Treatment.*—At the commencement of the disease we may make the attempt,

in suitable cases, to check the process by local depletion and by ice; but, as soon as suppuration or gangrene begins, the case becomes a surgical one. Now and then the threatening asphyxia demands tracheotomy.

## CHAPTER IX.

### ANOMALIES OF DENTITION.

(*Difficult Dentition.*)

THE processes of dentition play so important a rôle in the disorders of childhood that we feel obliged to discuss the subject, at least briefly.

The first appearance of any of the milk-teeth usually takes place when the child is seven to nine months old; it may, however, occur either earlier or later than this period. As a rule, the two lower central incisors are cut first; then the upper central incisors appear, a few weeks later, and next the lateral incisors of the upper jaw. In the beginning of the second year come the lower lateral incisors, and almost simultaneously the four anterior molars. The four canine, or "eye" and "stomach" teeth, are cut in the second half of the second year; and last of all comes the eruption of the four posterior molars. The first dentition is

FIG. 33.

therefore completed by the end of the second or in the beginning of the third year, with the development of all the twenty milk-teeth. The accompanying diagram (Fig. 33), after Vogel, represents the order in which the separate teeth appear. In the fifth or sixth year the milk-teeth begin to be replaced by the permanent teeth of the second dentition.

"Trouble with teething," however, almost invariably refers to anomalies of the first dentition.

Noticeable delay in teething is frequent in weakly, and particularly in rachitic children. In such cases, sometimes, all the teeth are not cut till the end of the third year.

On the other hand, it sometimes happens that certain teeth appear very early, or even are present at birth. If an abnormally early tooth is only loosely inserted in the gums, it should be removed with the forceps; for it interferes with nursing, and injures the opposing surface of the mouth. But if the tooth is firm in its place, we let it be.

During the eruption of the teeth there is in every child considerable redness of the mucous membrane and an increased flow of saliva. The child evidently feels an itching in the mouth, and therefore a constant desire to bite something. This simple catarrh is sometimes accompanied by a slight rise in temperature. Occasionally there is a severe stomatitis, with which thrush may be associated. These troubles should be treated as already described.

In consequence of the salivation, and the large amount of saliva which is swallowed, in which the various processes of decomposition are apt to develop, we often see gastro-intestinal diseases in teething children. In most children a temporary and mild diarrhœa occurs. We should be particularly careful at this period about the child's nourishment, and in treating any marked gastro-intestinal symptoms. Experience shows also that teething children are unusually liable to simple or even capillary bronchitis, and catarrhal pneumonia.

Nervous disturbances are often referred to dentition. The most important

symptom of this kind is eclampsia. The attacks are sometimes called "teething-convulsions." Although the laity go too far in ascribing all sorts of nervous disorders to teething, still experienced specialists do recognize the possibility of such an origin for many cases. Some of the convulsions may in fact be regarded as reflex (*vide infra* the chapter on the convulsions of children, page 779).

When the upper canines, or "eye-teeth," are being cut, there is sometimes a unilateral purulent conjunctivitis, which is perhaps to be explained as an extension of the inflammation by way of the antrum of Highmore and the nostrils.

Eczema and other cutaneous eruptions have been often ascribed to dentition; whether justly, is doubtful.

There is, of course, no special treatment for difficult dentition; and the various disturbances which it may indirectly produce are to be treated on general principles.

## SECTION II.

### DISEASES OF THE SOFT PALATE, TONSILS, PHARYNX, AND NASOPHARYNX.

#### CHAPTER I.

#### SORE THROAT.

(*Tonsillitis. Angina.*)

**Etiology.**—Acute inflammation of the soft palate and tonsils, in its various forms, is one of the commonest of diseases. Almost everybody has had personal experience with it. It is chiefly a disease of early life, being infrequent after the thirty-fifth year. Individual predisposition to it varies greatly. There are persons who have one or more attacks almost every year, while with others attacks are rare and insignificant. In many instances exciting causes have evidently been potent. Chief among these is catching cold; the sufferer has had wet feet, or has been talking in a damp, cold atmosphere. Most cases, therefore, occur in cool weather, although now and then attacks may occur in the hottest days of summer. Again, direct injuries of the pharynx may produce the disease, e. g., the smoky atmosphere of inns, combined with loud talking or shouting; the inspiration of poisonous vapors; cauterization of the mucous membrane with concentrated acids, alkalies, and other chemical agents; and burns.

[Especially when tonsillitis recurs in an individual, or attacks several members of the same household about the same time, it is well to have the drainage carefully examined. The precise connection between bad drainage and sore throats we do not know, but that they are often connected there seems to be no doubt.]

Frequently the inflammation is due to extension from neighboring parts, as in coryza, laryngitis, and stomatitis. In many cases both affections are simultaneous results of one common cause.

Finally, sore throat may be a symptom of many acute infectious diseases, such as scarlet fever, measles, small-pox, and erysipelas. It is also very probable that at least some of the primary cases of sore throat are to be regarded as a special acute infectious disease; but this has not yet been really proved.

To distinguish between an inflammation of the soft palate by itself and an affection of the tonsils is not practicable. In most cases the tonsils are the stronghold of the disease; less often we find the inflammation limited to the soft palate.

**Clinical History.**—The most important subjective symptom of sore throat, and that by which it is usually first recognized, is the difficult and painful deglutition. The pain is sometimes manifest before any objective changes are to be seen. It may in a severe case be very violent and distressing. The pain has a "darting" character, or sometimes is "burning"; and it is most acute whenever the patient swallows, although in well-marked cases it seldom entirely intermits. Swallowing is not only painful, but it is laborious; it requires more than usual effort and time. The patient feels constantly as if he had to swallow a big lump. This sensation is worse if the tonsils are swollen. It is a matter of experience that not infrequently an "empty" swallowing hurts more than swallowing a liquid or some half-solid substance.

Talking is also difficult. Every word may be painful, so that the patient expresses his wishes as briefly as possible. Even in a mild case, speaking for any length of time will produce a burning pain in the throat. The impaired mobility of the soft palate often prevents the complete cutting off of the nasal passages in talking, so that the voice has a nasal twang; and often it sounds as if the patient were talking with his mouth full: he has the "voice of sore throat."

Further local discomfort results from the mucus and saliva collecting in the mouth. Salivation is not infrequent, probably as a result of the stomatitis usually present. In other cases the patient complains that his mouth feels dry and sticky. Frequently there is a persistent bad taste in the mouth, and the breath is disagreeable.

With these local disturbances, more or less severe constitutional symptoms are almost always conjoined. Indeed, these latter may begin a day or two earlier than the local symptoms. The patient is indisposed, languid, has anorexia and headache. The general disturbance may be surprisingly great in comparison with the slight objective changes in the tonsils.

There is fever in most of the well-marked cases; it may even be quite high. Temperatures of 103° or 104° (39.5°–40° C.), or even higher, are not rare. Sore throat can not be said to have one particular type of fever. Usually the fever appears rather abruptly, remains high for several days, with an occasional slight interruption, and then falls with equal abruptness to normal again.

The entire attack usually lasts only a few days, seldom more than a week. Even where a person is quite ill for several days, convalescence is almost always rapid and complete—that is, if the patient has a good constitution.

Special complications are very infrequent, except that the neighboring parts—the larynx, mouth, and throat—are not seldom involved. Herpes labialis is quite frequent. Beyond this there is nothing to mention.

#### VARIOUS FORMS OF SORE THROAT.

The symptoms thus far mentioned are much the same in all cases of sore throat, varying only in intensity and duration. But the objective changes to be observed in the soft palate and tonsils are noticeably different in different cases. Whether the aetiology differs also we have no certain information. In some instances it seems probable that it does.

We shall distinguish five chief varieties of acute sore throat. Transitional forms are, however, by no means rare. Genuine diphtheria, which is a specific, acute, infectious disease, and has already been discussed, does not need to be brought up again here.

1. **Catarrhal Sore Throat** (*Simple Catarrhal Inflammation of the Mucous Membrane of the Soft Palate*).—There is a more or less vivid reddening of the mucous membrane, either uniform or in patches. The swelling is most marked

in the pillars of the fauces and the uvula. The surface of the tonsils is likewise reddened; their size may be somewhat increased, or remain unchanged. The mucous membrane of the palate and uvula may be covered here and there with a thin layer of muco-pus, which can easily be wiped off. The tonsils may present small, superficial erosions, scattered about. These little ulcers are apt to lie at the openings of the follicles. The small "blisters" which are often seen on the mucous membrane of the soft palate may be caused in various ways. Either they are mucous glands or solitary follicles, swollen; or, rarely, they are real vesicles filled with a clear fluid and produced by a raising up of the epithelium. The cervical lymph-glands are usually but slightly swollen, if at all.

This is the common and mildest form of sore throat; and it may be over in a day or two. In some instances, however, it causes considerable local and general discomfort; but the disease seldom lasts longer than five to eight days.

**2. Follicular Tonsillitis.**—In this form there is not only more or less catarrhal inflammation of the soft palate, but a decided swelling of one or both tonsils. On the reddened surface of these swollen bodies are whitish-yellow spots, varying in number from two or three to ten or more, and corresponding to the follicles. These spots are often seen to be plugs projecting from the openings of the follicles. It is usually easy to press out the pasty contents of the follicle, represented by the white speck, with a spatula. The microscope shows it to consist of numerous epithelial cells and pus-corpuscles, bacteria, and detritus, and sometimes there are also crystals of the fat acids and cholesterine. The pus-corpuscles may so predominate that we may have small follicular abscesses, which, on being opened, leave superficial ulcers behind. The parenchyma of the tonsil is swollen with a serous and cellular infiltration, increasing the bulk of the part. The trouble is usually bilateral, though often more marked and extensive on one side than on the other. In the severer cases the cervical lymph-glands are swollen.

The clinical symptoms do not differ essentially from those of the other forms. The attack may be mild or severe. Usually the contents of the follicles are discharged after a few days, and the tonsils become normal again. Yet the contents may be retained some time, and become calcified. It is not a rare thing to find such plugs in the tonsils of those who are subject to sore throat. Timid and hypochondriacal individuals are sometimes badly frightened by expectorating these old chalky plugs, which they believe to be "tubercles"! From an etiological standpoint, follicular tonsillitis is in most cases entirely distinct from genuine diphtheria; still it is noteworthy that precisely at the time of diphtheria epidemics follicular tonsillitis is remarkably frequent. It might, after all, be possible that the mildest degrees of diphtheria present themselves in the garb of an apparently simple follicular tonsillitis. The latter is very probably an infectious disease.

**3. Tonsillar Abscess (Parenchymatous Sore Throat).**—In this form the swelling of the tonsils is the most striking symptom. They may be more than twice their natural size. The anterior pillars of the fauces are pushed forward and become convex. The swelling extends so far toward the median line that the tonsil touches the uvula; or, if the affection is bilateral, the two tonsils press against each other, grasping the uvula between them, or pushing it forward. The soft palate is very much reddened, particularly at first. Its surface is usually thickly covered with mucus. If this be wiped off, the mucous membrane is seen to have a moist, oedematous luster. The mucous membrane of the tonsils not infrequently suffers a superficial necrosis. Follicular and parenchymatous tonsillitis are often combined.

In well-marked cases of abscess the local discomfort is usually great. The patient is in a pitiable condition; he can neither talk, nor swallow, nor gargle.

The few words which he painfully utters have in an extreme degree the nasal quality of the "voice of sore throat."

In the milder cases the trouble seldom lasts but a few days before the swelling goes down, and the discomfort and usually rather high fever gradually abate. In other cases, however, a tonsillar abscess forms, usually on only one side. The mucous membrane bulges out more and more in one spot; fluctuation is detected; and, finally, the abscess breaks. With the discharge of the pus the pain is relieved very rapidly, or it may vanish at once. The rest of the tonsil soon regains its former size, and in a few days the patient is well. Relapses are possible, but rare.

Parenchymatous or (as it is called) phlegmonous sore throat, in which the soft palate and not the tonsil is chiefly affected, is infrequent. Its usual cause is some severe external injury, like burns, and cauterizations with concentrated acids or alkalis. The swelling extends deep down into the submucous tissue. The uvula may have the diameter of one's finger. There is intense hyperæmia. Sometimes there are hæmorrhages into the mucous membrane: this is called hæmorrhagic sore throat.\*

There are also a peri-tonsillar and a retro-tonsillar abscess, which from a clinical standpoint are not essentially different from the more common form. They are almost always unilateral, and are due to a suppurative inflammation of the peri-tonsillar connective tissue, lying between the tonsil and one of the pillars of the fauces, usually the anterior one.

4. **Necrotic Tonsillitis**, or *Necrotic Sore Throat*.—In this form the tonsils are chiefly involved. The pillars of the fauces and the uvula are but slightly affected with a simple catarrhal inflammation. The tonsils are, as a rule, moderately swollen, seldom attaining great size. The mucous membrane covering them presents a whitish or grayish-white discoloration, often quite extensive, and most marked on the side toward the uvula. These spots are often erroneously said to be a white "coating"; but a more careful investigation shows that there is in reality a necrosis. The process may be superficial; sometimes it reaches quite deeply into the structure of the mucous membrane. It is not possible to pull off this white matter, as one can loosen croupous membranes, although little bits may perhaps be scratched off with a spatula or a pair of forceps. These particles are found, on microscopic examination, to be made up merely of detritus, bacteria, epithelium, and pus-corpuscles. The necrosis is almost invariably confined to the tonsils, and a sharp boundary-line separates it from the reddened and inflamed pillars of the fauces. After a few days the slough may come away, leaving behind an ulcer, which, though usually shallow, has sometimes a considerable depth. This generally cleans up rapidly. In severe cases, however, the floor of the ulcer consists for a number of days of a dirty necrotic material, which comes away only gradually. The worst cases may be properly called "gangrenous tonsillitis."

Necrotic tonsillitis is almost always attended by considerable fever and marked constitutional disturbance. Children particularly seem very ill in the first days of the attack. The cervical glands are usually swollen, but seldom as much so as in genuine diphtheria.

Despite the rather ominous commencement, the disease does not last a great deal longer than the other forms of sore throat. It seldom continues more than five to eight days before a speedy convalescence begins.

\* Another form with the same name occurs where there is violent tonsillitis with necrosis or gangrene. There is also a necrotic, hæmorrhagic sore throat accompanying scurvy, leukaemia, and analogous diseases.

The necrotic tonsillitis is distinguished from the follicular form by the greater area of the white or grayish-white spots. Still it should be particularly noted that sometimes combinations of these two varieties, or transitional forms, occur.

**ÆTIOLOGY.**—In our opinion, necrotic tonsillitis is in many instances an entirely different disease from genuine diphtheria. On the other hand, our experience in several epidemics of diphtheria in Leipsic and Erlangen has taught us that in all probability mild cases of genuine diphtheria of the tonsils do occur, and that these objectively resemble necrotic tonsillitis. This is the only way to explain what other physicians as well as ourselves have often observed—namely, that necrotic tonsillitis appears not infrequently in families at the same time with severe cases of genuine diphtheria. Besides, these cases of necrotic tonsillitis are sometimes followed by the characteristic “diphtheritic” paralysis.

[The reader will observe that the author distinctly admits the frequent impossibility of distinguishing between his necrotic and croupous forms of sore throat and diphtheria. It is furthermore stated that the follicular form occurs in combination with either or both of the necrotic and croupous forms, the vague nature of which is thus apparent.

A membrane or membraniform layer which is not confined to the tonsils, or which is seen on the soft palate or pillars of the fauces alone, should be regarded with great suspicion. A few days' isolation can do no harm in such a case, and may save bitter regrets.

Similar deposits limited to the tonsils consist not infrequently of follicular secretion which has coalesced; careful examination will show the follicular origin in these cases.

A protest should be entered against the use of the term “diphtheritic sore throat,” so often applied to severe simple inflammations as well as to mild or doubtful cases of diphtheria. A case is either one of diphtheria or it is not. It is our duty neither to excite needless alarm nor to encourage a false security. In doubtful cases the only safe way is frankly to express the doubt and prepare for the worse alternative.]

**Diagnosis and Prognosis.**—It is never very difficult to recognize a sore throat, and a little practice makes it easy in most cases to decide what particular variety is present, if we examine the objective changes carefully. It is very important in practice to distinguish diphtheria from the benign forms of inflammation. Follicular and necrotic tonsillitis are very frequently mistaken for diphtheria—an error which explains the success of a large number of remedies said to cure diphtheria. Many physicians call every case of sore throat, where there is anything white to be seen, “diphtheria.” Certainty in diagnosis of genuine diphtheria can only be gained by practice; no description, however complete, can take the place of personal observation. It may be a help to remember that in both follicular and necrotic tonsillitis the white spots are usually limited to the tonsils, while in croupous sore throat the deposits are generally from the very first also situated upon the pillars of the fauces and the uvula. The white spots of the follicular variety can generally be recognized by their arrangement. The plugs are seen projecting from the follicles. In necrotic sore throat there is never a separable croupous membrane with its characteristic histological structure, but there is simply a superficial necrosis of the mucous membrane and parenchyma. In doubtful cases the condition of the cervical lymph-glands is not unimportant; as a rule, they are much more affected in diphtheria than in the benign cases. Inasmuch as we have seen that the milder forms of tonsillitis may be ætiologically related to diphtheria, it is well in practice to make a guarded prognosis, even in cases of follicular and necrotic angina, particularly in children. And we should always isolate the patient from other children.

**Treatment.**—These troubles run so favorable a course that active treatment is very seldom needed. The gargle usually prescribed generally gives the patient more discomfort than relief. The most common prescriptions are: Solutions of potassic chlorate (5-10:300), of alum (5-10:500), or of borax (10:300); salt and water; and weak solutions of carbolic acid or of permanganate of potash. To paint the parts is a useless and now almost obsolete proceeding. Inhalations of spray are better, with alum, tannin, or carbolized water. It is beneficial to put a cold wet compress around the throat. Children must be kept in bed, and adults are generally forced to go to bed, if the constitutional symptoms are well marked.

In parenchymatous tonsillitis, ice will sometimes alleviate the pain. Often, however, the patient can not bear it. If there is evident fluctuation, we can make an incision with a spear-pointed bistoury, after guarding a portion of the blade with sticking-plaster. Great relief follows; and, even if there is no abscess, scarification of the tonsils, if they are excessively swollen, usually lessens the pain. The operation causes little discomfort.

We may add that if a person is subject to sore throat, he can lessen his liability to attacks by hardening his skin through the use of cold baths.

## CHAPTER II.

### CHRONIC HYPERTROPHY OF THE TONSILS.

CHRONIC hypertrophy of the tonsils occurs not only in those who have had repeated attacks of tonsillitis, but also in cases where no occasion for it can be found. Even in childhood there may be well-marked hypertrophy, which must be due to a congenital predisposition.

The condition is at once revealed by inspection. There may be no signs whatever of any acute or chronic inflammation, or there may be an accompanying chronic pharyngitis. The tonsils bulge out in two great lumps. They may be so large as to touch the uvula on each side. Histologically, there is a genuine hypertrophy of the organ—that is, an increase of all its component tissues.

In many cases, where the swelling is moderate, there is no discomfort. The possessor of the tonsils is not aware that they are enlarged. In other cases the hypertrophy proves of clinical importance, inasmuch as all forms of sore throat are found to occur more frequently if the tonsils are enlarged, and to cause more trouble when they do appear. The hypertrophied organs may also be the seat of a chronic catarrh, which by extension gives rise to chronic nasal catarrh, catarrh of the Eustachian tubes, or hoarseness.

If the hypertrophy is considerable, the local discomfort may be quite marked. Swallowing is rendered difficult, if not painful. Frequently there is evident dyspnoea. The patient has to breathe through his mouth, and sometimes when asleep snores and snorts in a way to frighten one. Children are particularly apt to suffer in this manner. Many instances of *pavor nocturnus*, or "night terrors," in children are referable to this cause. We have already mentioned that cases of bronchial asthma sometimes seem to be connected with hypertrophy of the tonsils (see page 171).

**Treatment.**—The attempt to reduce the enlargement by applying lunar caustic, tincture of iodine, etc., usually fails. If there is much distress, if the patient is subject to frequent sore throats, or if the hypertrophy of the tonsils keeps up a chronic nasal or pharyngeal catarrh, then the simplest remedy is to remove the tonsils. The operation is free from any danger. The extirpation can be accom-

plished either with the tonsillotome or with scissors and forceps. The latter way is the simpler, and is almost equally easy.

### CHAPTER III.

#### CHRONIC PHARYNGITIS.

**Ætiology.**—It is not practicable to distinguish between chronic catarrh of the soft palate and of the pharynx, for, as a rule, the two are combined. Sometimes the condition is the result of repeated acute attacks; sometimes—and probably oftener—it is due to persistent, injurious, local influences. A large number of cases originate in bad habits, or in abuse incident to certain vocations. Examples are seen in smokers, drunkards, singers, preachers, teachers, and men who work out-doors. In talking and singing, the soft palate is strained; or the disease is excited by breathing cold or impure air, or by such chemical irritants as alcohol or tobacco. In many cases, chronic pharyngitis follows chronic rhinitis or chronic laryngitis. The general passive congestion due to cardiac disease or pulmonary emphysema may sometimes promote the development, or prolong the existence, of a chronic pharyngitis.

**Symptoms.**—The local discomfort is often slight. The patient gets used to it, and does not mind it except when there is some exacerbation. It becomes a more important matter if the calling of the patient is interfered with, as in a preacher, singer, or teacher.

Deglutition is seldom impaired. There is often, however, a constant feeling of dryness, or burning, or scratching in the throat. The patient has to clear his throat frequently, and often acquires an habitual, short, sudden cough, which may be dry. The uvula becomes so long that its tip rests on the tongue or the posterior wall of the pharynx; and this gives rise to a peculiar and disagreeable sensation of tickling. All these uncomfortable feelings are temporarily increased if anything affects the throat unfavorably; and they are generally at their worst on rising in the morning, apparently because the mucous membrane has become dry, or a collection of tough mucus has formed during the night. Every one knows how drunkards have to hem and cough mornings, so that often they almost strangle or vomit.

On inspection, we generally find the mucous membrane reddened. Very often a number of dilated and tortuous veins are visible both on the soft palate and in the back of the throat. Of equal frequency is the appearance of numerous small gray projections, corresponding to swollen follicles or hypertrophied mucous glands. This is called granular pharyngitis. Small follicular ulcers are not infrequent. Exceptionally there are more extensive catarrhal ulcers. The mucous membrane of the posterior wall of the pharynx may present patches of opaque or thickened epithelium, giving the surface a grayish-white appearance.

Frequently chronic pharyngitis is combined with chronic laryngitis, evidenced by hoarseness; or with posterior nasal catarrh, or catarrh of the Eustachian tube, producing deafness and ringing in the ears.

#### VARIETIES OF CHRONIC PHARYNGITIS.

1. **Chronic Catarrh of the Naso-pharynx, or Chronic Posterior Nasal Catarrh.**—This has the same ætiology as the ordinary form. It is practically important because the nose and ear are frequently involved.

The anatomical changes are essentially those already depicted under chronic pharyngitis. The region affected can not be seen by direct inspection, so that accuracy in diagnosis requires the use of a nasal speculum (see particulars in the works mentioned on page 125). The ordinary examination of the throat may reveal a condition which is quite characteristic of posterior nasal catarrh: a collection of muco-pus, or of firmly adherent dry crusts, rests upon the posterior wall of the pharynx, and can be seen to extend upward toward the naso-pharynx.

The local discomfort is somewhat similar to that experienced in chronic pharyngitis. There is a scratchy feeling, or a feeling as if there were a foreign body in the back of the throat, accompanied by a constant desire to blow the nose, hawk or cough. Dried and decomposing secretion often causes extremely foul breath. There is often also vertigo, and occipital headache.

In many cases the nostrils are stopped up. The posterior opening of the nostrils is closed in part by the swelling and hypertrophy of the mucous membrane, and in part by the accumulated secretions. The patient, therefore, usually has to breathe through the mouth. The ear is frequently involved. The catarrh extends into the Eustachian tubes and the tympanic cavity, or the opening of the tubes is occluded with the secretions. For a detailed consideration of the deafness, tinnitus, etc., thus produced, consult works on otology.

**2. Pharyngitis Sicca**, or "*Dry Atrophic Catarrh of the Throat and Naso-pharynx.*"—This name is applied to an atrophy of the mucous membrane, which sometimes is spontaneous and sometimes is a sequel of chronic pharyngitis. The whole mucous membrane of the pharynx and the naso-pharynx (seen with the rhinoscope) seems pale, smooth, and perfectly dry, and has a peculiar luster, as if varnished. Here and there tortuous veins project from the general anæmic surface.

If an opportunity is afforded to examine the mucous membrane microscopically, it will be found that the atrophy involves all the elements of the tissue, though the follicles and mucous glands suffer most.

This condition may not cause any symptoms, but, in many cases, the patient suffers constantly and considerably. The chief trouble is a feeling of dryness in the throat, rendering deglutition difficult or even painful. There is also a constant desire to clear the throat. The secretion hawked up may be scanty and tough or more abundant, and it is often tinged with blood. Actual coughing may also be due to pharyngeal trouble ("throat-cough"). Talking is often rendered difficult, the voice grows weak and it becomes easily tired. In severe cases there is considerable general debility. Not infrequently pharyngitis sicca is associated with atrophic rhinitis (q. v.), but it occurs also in cases where there is no nasal disease.

The disease is most frequently seen in the elderly, but it also occurs in children and young persons. It is especially common in ill-nourished individuals or in those who are suffering from such diseases as tuberculosis or chronic nephritis.

**3. Hypertrophic Catarrh of the Pharynx and Naso-pharynx.**—An opposite condition of hypertrophy sometimes results from chronic catarrh. The changes consist mainly in hyperplasia of the lymphatic tissue, and they are usually termed "adenoid growths." The choanæ and the posterior extremity of the nasal septum may be almost completely hidden by these growths, as they extend down from the roof of the pharynx in grayish-red, uneven masses. In many cases the hypertrophy seems to originate chiefly in Kölliker's "pharyngeal tonsil."

The adenoid growths are especially common in childhood. The symptoms consist in a change of the voice (which loses its reverberating quality and becomes nasal), frequent snuffling and hawking, and a tough mucous secretion, often

tinged with blood. Not infrequently there is headache. Of greater importance is ear-trouble, which is often occasioned by the growths.

An accurate diagnosis requires rhinoscopy. Positive results are also often obtained by palpation. The index-finger, being passed backward and bent upward, can touch the protuberances and the enlarged pharyngeal tonsil in the naso-pharynx.

**Prognosis.**—The prognosis in all forms of chronic pharyngeal catarrh should be somewhat guarded, for all severe cases are very obstinate and can seldom be permanently cured. Success may be depended upon only in cases where all unfavorable influences can be completely removed. We may afford great relief, but there will be a persistent tendency to acute exacerbations and to relapses long afterward.

**Treatment.**—Many of the milder cases never apply to a physician. The patient uses some domestic remedy or gargle, or becomes so accustomed to the disagreeable sensations that he does not consider it necessary to do anything in particular about them.

The treatment of a well-developed case requires great patience and persistence on the part of all concerned. If there is some underlying disease, such as pulmonary or cardiac disease, that must be treated. All exciting causes must be avoided. Energetic local treatment is also indispensable. This has been greatly elaborated by specialists, and for the many details we must refer to their writings; but the following remarks will meet the requirements of ordinary practice:

Gargles are seldom satisfactory, for they never reach farther than the soft palate. Inhalations are better; we can use solutions of alum or tannin, or, in mild cases, of common salt. Still more efficient is the painting of the entire surface of the pharynx with some concentrated solution. The physician usually has to perform this, although some patients learn to do it for themselves. Proper solutions are: Argentic nitrate, five or ten per cent.; tannin, eight to twenty per cent.; tincture of iodine, either pure or diluted; or iodized glycerine, composed of pure iodine, parts 1.5; iodide of potassium, 5; glycerine, 500. These applications must reach all the diseased surface. If the naso-pharynx is involved, the brush must accordingly be bent upward, to reach that region. For this a mirror may be needed. It is very important to make the applications to the mucous membrane itself, freed from any interposing secretions.

In the treatment of chronic posterior nasal catarrh the nasal douche (*vide* Diseases of the Nose) plays an important part. It should be used two or three times a day. It not only removes the collected secretions, but is a means of making local applications. The instrument is merely a fountain-syringe. The nozzle must be of a size to fill the nostril completely. The force of the current should always be moderate, and the patient's head should be sharply flexed forward. The fluid used—the best is a one-per-cent. solution of sodic chloride or bicarbonate—must have about the temperature of the body. Other medicated solutions must be very weak, such as sulphate of zinc, 1 to 1,000.

The insufflation of powders into the throat can be made through any small glass tube, three to six times a week. Alum or tannin may be used, either pure or mixed with equal parts of pulvis gummosus [P. G., made of gum-arabic, three parts; licorice-root, two parts; and sugar, one part]. For the naso-pharynx, a bent tube of glass or hard rubber is to be introduced through the mouth. There are numerous "insufflators" to be had at the instrument-makers.

Many baths enjoy a great reputation for the cure of chronic pharyngitis. Besides Ems, there are Reichenhall, Kreuznach, Salzungen, the cold sulphur springs, such as Weilbach, and many others. Good results are also achieved in Kissingen and Marienbad, if these places are favorable to the patient's general constitution.

In pharyngitis sicca, the nasal douche with a one-per-cent. salt solution is to be recommended. It is sometimes also beneficial to paint the parts with solution of argentic nitrate, iodized glycerine, etc. Many irritating influences which do harm in common pharyngitis seem sometimes actually to benefit this form—such as smoking and taking snuff.

In treating the hypertrophic forms of pharyngitis and the adenoid growths, cauterization with nitrate of silver suffices for the milder cases alone. A thorough and permanent cure can be achieved only by removing the growths with the galvanic-cautery.

[To Hooper, of Boston, belongs the credit of showing that a radical operation for the removal of adenoid growths of the naso-pharynx can safely be done under anaesthesia. The blood does not, as was feared, run into the air-passages, but either into the stomach or outwardly. Anaesthesia thus renders it possible to scrape away with the finger or tear away with forceps the hypertrophied tissue at one sitting, and to do it in the child before secondary changes have taken place in the facial expression, the jaw, the ears, or the form of the chest.]

#### CHAPTER IV.

##### RETROPHARYNGEAL ABSCESS.

RETROPHARYNGEAL abscess is formed by a suppurative inflammation of the connective tissue lying between the posterior wall of the pharynx and the spinal column. It is a serious disease, although a rare one. If unrecognized, it proves fatal in many instances; while, if a correct and timely diagnosis is made, the patient can usually be easily cured. It is commonest in childhood, and before the second year. It almost always appears as a primary, acute disease, without any special cause being evident. Probably the agents which excite the inflammation penetrate into the tissue from the pharynx. The idea that the inflammation originates in the small lymphatic glands which lie in front of the vertebræ lacks proof as yet.

The disease attacks not only weakly children, but those who have been perfectly healthy and vigorous. The child grows restless and fretful, and does not nurse well. Apparently, deglutition soon becomes painful, but one can not be certain about this except in older children. Generally, the respiration quickly takes on a peculiar stertorous character, particularly during sleep. Mucus collects in the mouth and throat. Upon swallowing, there is often regurgitation through the mouth or nose, or some of the food gets into the windpipe and causes violent coughing. The lymph-glands of the jaws are usually somewhat swollen, and the neighboring parts may seem slightly oedematous. After a week or two the dyspnoea gradually increases. Respiration becomes more and more laborious, with loud rattling, and the signs of stenosis. The jugular veins become distended, the lips cyanotic, and portions of the thorax are retracted during inspiration. The voice is feeble, and may be hoarse and indistinct.

The correct interpretation of these symptoms, which are common to various disorders, requires a careful examination of the throat. It must be confessed that this has its difficulties in an infant. Still, we can sometimes see distinctly a swelling in the posterior wall of the pharynx. This may be either in the median line or on one side. All doubt is removed by digital examination, in making which, however, we must insert a wedge between the teeth, to avoid being bitten. The finger detects fluctuation.

The diagnosis once established, the abscess must be opened at once. We should not delay, even if the dyspnœa has not yet become extreme. To use the finger-nail for the purpose, as has been recommended, is permissible only in an emergency. As a rule, incision is made with a bistoury, of which all but the point is guarded with sticking-plaster. The left index-finger is placed upon the abscess, and used as a guide. Meanwhile, the child's head is kept upright, and, as soon as the cut is made, bent over forward. The pus pours out in abundance. It is advisable to syringe out the mouth repeatedly with lukewarm water. The threatening symptoms vanish almost instantly upon the escape of the pus. Exceptionally, the abscess refills and requires a second incision.

If the trouble is not correctly diagnosticated, or if the abscess is not opened promptly, the patient may suffocate. Or the abscess may burst spontaneously; then there is either speedy recovery, or asphyxia from the pus filling the larynx. In some instances, where a retropharyngeal abscess has not been properly treated, the pus has gravitated far down into the neck and posterior mediastinum. The recognition and incision of the abscess may prove very difficult if from the start it is situated lower down in the throat than usual.

Analogous to this acute idiopathic abscess of which we have been speaking is the chronic abscess due to caries of the cervical vertebræ. This should not be opened unless there is danger of asphyxia.

Retropharyngeal abscesses sometimes occur in pyæmia or other severe acute infectious diseases, but have hardly any interest except to the pathologist.\*

### SECTION III.

#### DISEASES OF THE ŒSOPHAGUS.

##### CHAPTER I.

#### INFLAMMATION AND ULCER OF THE ŒSOPHAGUS.

**Ætiology and Pathology.**—The various forms of œsophageal inflammation and ulceration are not of very great clinical importance. The processes are seldom of a severe grade, or, if so, they are generally a part of some complicated disease, to which they seldom contribute prominent symptoms. Very likely the milder forms of inflammation occur frequently, but the symptoms are hardly ever characteristic.

A simple catarrhal inflammation of the œsophageal mucous membrane may be caused by swallowing substances which are injurious mechanically, chemically, or from their temperature. It may also occur in the general infectious diseases, such as typhoid and typhus fevers, and the acute exanthemata. Any inflammation of neighboring tissues may extend into the œsophagus. Chronic catarrh is seen in heart disease, from the passive congestion. It is also found in the vicinity of other chronic œsophageal diseases, particularly cancers and diverticula (*vide infra*).

The acute catarrh is distinguished by not having the usual increase of secretion. The epithelium grows spongy, as a rule, and is cast off more rapidly than

\* Tuberculosis of the pharynx is spoken of in the chapter on pulmonary tuberculosis, p. 226. New growths in the mouth or pharynx belong to the domain of surgery.

usual, so as to suggest the name of a desquamative catarrh. It is in only a few cases that the scanty mucous glands become swollen and look like papules upon the surface of the membrane; this form is called follicular catarrh. In limited areas the desquamation may be complete, giving rise to small catarrhal erosions. Likewise, the swollen follicles may break down into small follicular ulcers.

In chronic catarrh there is a moderate increase in the secretion of mucus, and a marked thickening of the epithelium. In very protracted cases actual papillomata may finally be formed. In some cases ulcers are seen.

Croupous and diphtheritic inflammations of the œsophagus are very rare. We have already said that the specific pharyngeal diphtheria frequently extends into the larynx, but only exceptionally into the gullet. Still, we have ourselves seen in a child a stricture in the upper third of the œsophagus, which was said to have been a result of a severe attack of diphtheria. Isolated cases of diphtheritic œsophagitis have also been seen in connection with severe infectious diseases, such as typhus, typhoid, small-pox, cholera, pyæmia, and pulmonary tuberculosis, as well as in the course of Bright's disease and cancer. In variola it is not unusual for pecks to appear upon the œsophageal mucous membrane.

A purulent, phlegmonous œsophagitis now and then attacks the submucous layer. It may be either diffuse or circumscribed. The mucous membrane is dissected up from the muscular layer by the pus, and pushed inward, so as to diminish the lumen of the œsophagus more or less. Most of the cases end by the discharge of matter into the tube, when complete recovery may ensue. If the mucous membrane, however, has been extensively undermined, Zenker states that a fissure-like cavity may be left, even after healing has taken place. Its walls grow smooth, and finally acquire a layer of fresh epithelium.

Purulent œsophagitis is caused either by the presence of foreign bodies in the œsophagus, or by purulent inflammation in neighboring parts, as in glandular abscess, vertebral abscess, or laryngeal perichondritis. It has now and then resulted from the action of concentrated acids and the like upon the mucous membrane.

The action of corrosive poisons (corrosive œsophagitis) is to cause necrosis of the tissues, which in its turn produces inflammation. The inner surface of the œsophagus is converted into a rotten, hæmorrhagic, sloughing mass, of a dirty gray or almost black color. The muscular layer itself may be partly destroyed. If death does not occur speedily, the necrosed portions come away, leaving extensive purulent ulcers behind. These, if they heal at all, cause large cicatrices and stenosis.

**Symptoms.**—The milder cases, as we have stated, produce almost no distinctive symptoms. Possibly there may be pain along the œsophagus, or at some one point in it, during deglutition. In a more severe case the pain may be great; but the other symptoms are usually too grave for this to excite special attention. Laborious deglutition, and the feeling as if the food were inclined to stick in the throat, result from implication of the muscular layer. A diagnosis of the particular form of œsophagitis is attainable only when the ætiology guides us to it.

Treatment must be purely symptomatic. No solid food should be taken. The pain is to be allayed by bits of ice, or by morphine.

## CHAPTER II.

## DILATATION OF THE ŒSOPHAGUS.

## 1. Diffuse Dilatation.

DIFFUSE, spindle-shaped dilatation of the œsophagus is observed as a result of stricture of the cardiac orifice. At first the muscular coat hypertrophies as the orifice contracts, and is able to overcome the obstruction, so that there is no dilatation; but as soon as the muscles are paralyzed, and food collects behind the stricture, the dilatation begins and keeps on increasing. The ectasis is greatest at the lower end of the tube, as is natural from its mode of origin, and gradually diminishes upward.

There have been a very few well-substantiated instances of this diffuse spindle-shaped dilatation, without any demonstrable stenosis of the cardiac orifice. Their cause is unknown. Sometimes the walls of the œsophagus may have been rendered more yielding and less contractile by a precedent inflammation or other disorder. In other cases, some chance bend or distortion of the lower end of the œsophagus may have produced a mechanical obstruction. In some cases the exciting cause is said to be a blow on the chest, or the lifting of a heavy weight.

The symptom of this condition, when well developed, is a chronic difficulty in deglutition, lasting perhaps for years. The patient himself feels that most of the food he eats does not reach the stomach, but lodges higher up. Usually the food is soon afterward vomited, or rather gulped up. When there is stenosis of the cardiac orifice, the explanation of these symptoms is easy. It is much harder to explain the almost equal dysphagia where there is dilatation without stenosis. Sometimes a localized bulging of the wall causes the food to collect in that spot, and thus to obstruct the lumen. As is to be expected, the partial or complete hindrance to the ingestion of food results in marasmus.

If there is stenosis, it can easily be detected with the œsophageal sound, and all the symptoms thus explained. In the rare cases, however, of diffuse dilatation without stenosis, the use of the sound does not give us so much information. If the instrument passes readily into the stomach, we may safely exclude stricture; but, in one case of our own, we made an erroneous diagnosis of a diverticulum, because the sound sometimes glided readily into the stomach, and sometimes could not be passed. A pocket must have been formed at the lower end of the dilated tube, in which the sound caught.

The treatment is directed chiefly to the satisfactory nourishment of the patient; for the œsophageal trouble itself is dangerous only as it prevents the taking of food and leads to starvation. We do not speak of the initial lesion, if there be one, which causes the dilatation. If nourishment can be given through a stomach-tube, the patient almost invariably shows a rapid improvement, which lasts as long as the artificial feeding can be kept up. If, however, any cause prevents the introduction of the tube, we must resort either to nutrient enemata (*vide infra*)—and these will not support the system indefinitely—or we must make a gastric fistula. In the latter case the prognosis depends on the success of the operation and the nature of the original lesion.

## 2. Diverticula.

**Ætiology and Pathology.**—Circumscribed pouches in the wall of the œsophagus are termed diverticula. They are divided into two essentially distinct varieties, according to their mode of origin. Zenker has given them the names of pressure and traction diverticula.

The diverticulum due to pressure is extremely rare. It is caused by pressure upon the mucous membrane from within, by which some abnormally weak spot is forced outward. All cases that have been carefully examined thus far have shown that, histologically, the wall of the diverticulum is not the distended but otherwise unchanged wall of the œsophagus, but is composed exclusively of the mucous membrane and the thickened submucous coat. We are therefore obliged to suppose that the mucous membrane is pushed out like a hernia through some gap in the muscular coat. It is only about the neck of the diverticulum that any muscular fibers are found.

The original factor, therefore, in the occurrence of a pressure diverticulum is apparently to be sought in some circumscribed lesion of the muscular coat. As a result of several observations, it is established that a foreign body, sticking in the throat, may separate some of the muscular fibers and push the mucous membrane through the gap thus formed. Or a severe injury leads to a trifling rupture of the muscular coat, and then the food, as it is being swallowed, presses out the mucous membrane at this weakened spot. There are still many other cases where the true origin of the diverticulum remains obscure.

As soon, however, as the formation of the pouch has once begun, there are many influences to make it grow larger. Each successive bit of food, as it glides by, presses upon this yielding and inelastic spot. Gradually a little sac is formed, in which bits of food lodge. These exercise a constant pressure upon the walls of the pouch, and by their weight drag it bodily downward. The larger the pouch, the more it holds, and consequently the more it grows. Thus a pressure diverticulum of the smallest size originally may gradually attain to a diameter of four inches or more. The general shape of the diverticulum may approach the hemispherical, or it may be more cylindrical or pear-shaped.

It is remarkable that, with very rare exceptions, these pressure diverticula are always situated at the beginning of the œsophagus, or rather between it and the pharynx, and almost invariably affect the posterior wall. The pouch hangs, therefore, in front of the spinal column. It pushes out through the lowest fibers of the inferior constrictor of the pharynx; and the feebleness of this muscle is apparently a potent factor in determining the precise point of origin.

The cases thus far seen have been almost all in men, and at a rather advanced age. A few cases have occurred in children.

Traction diverticula are much more common, but in most instances have little interest except for the pathologist. They are not infrequently found unexpectedly at the autopsy. Rokitsansky, and later Zenker, have given explanations of their occurrence: some tissue, which has formed adhesions to the œsophagus, contracts and gradually pulls out the œsophageal wall in the shape of a funnel. Bronchial glands are apt to be the seat of the contractile change. These glands are situated near the bifurcation of the trachea, and accordingly the traction diverticula occur oftenest at this level. There may be two or three in one subject. They are rarely over a third of an inch in depth. From within, the mucous membrane, much wrinkled transversely, is seen to be drawn toward the apex of the diverticulum. The wall of the latter consists either of the mucous membrane alone, bulging out like a hernia, or of the mucous membrane covered by the muscular layer. Inasmuch as children quite often suffer from suppuration and caseation of bronchial glands, with subsequent shrinkage, we see why traction diverticula are frequent in children.

**Clinical History.**—The large pressure diverticula always cause grave symptoms, for they obstruct more and more each day the passage of food. At first there is scarcely any disturbance. Gradually, however, deglutition is impeded. A portion of the food lodges in the pouch, and is either wholly or in part regurgitated,

though perhaps not immediately. Decomposition is apt to take place in the contents of the diverticulum, giving rise to foulness of the breath and to nausea. The danger reaches its climax when the distended sac presses sidewise upon the œsophagus and closes its lumen, so that no food reaches the stomach. After protracted strangling and vomiting, the material may be in part ejected, and the patient enabled once more to swallow.

Of course the symptoms in individual cases depend upon the mechanical conditions present, and may vary greatly. Patients contrive all sorts of manipulations, by which they manage to get at least some portion of their food down. Such individuals may maintain a tolerable degree of nutrition for years, although they scarcely ever are in a normal condition. But at last some cause or other renders the amount of food ingested inadequate; whereupon a rapidly progressive marasmus sets in, and the patient will inevitably starve to death unless some relief is afforded.

The most valuable objective evidence in these cases is gained by the use of the œsophageal sound. If the sound enters the sac, its passage is impeded. If it happens to slip by the mouth of the diverticulum, it glides readily into the stomach. This varying result may sometimes be obtained at one sitting by repeated trials, and is of the greatest importance in making the diagnosis.

In some instances where the sac was large, a tumor in the neck has been observed at one side of the trachea, appearing after eating and disappearing when the sac emptied itself. Symptoms due to compression of the recurrent and phrenic nerves and of the blood-vessels have been noticed in some cases.

Auscultation of the œsophagus during the act of swallowing has been practiced, and, of late, attempts have been made to examine it with a speculum. Whether these methods of investigation will prove valuable for diagnosing diverticula, experience must determine.

The traction diverticula are usually of no clinical importance. They do not affect deglutition at all, and their size is too limited to permit any great accumulation of food in them. There is but one way in which they are dangerous: the apex of the funnel may undergo ulceration and perforation. A foreign body, like some bit of food, produces necrosis of the wall, by what is probably at first a purely mechanical irritation. The tissue ulcerates; and then the inflammation may gradually progress till it causes a severe and usually fatal illness. The most frequent event is perforation into a bronchus, followed by the aspiration of food and pulmonary gangrene. Or the perforation takes place into the pleural cavity, exciting an ichorous empyema. In other cases the pericardium or a large vein has been perforated. Many a case of apparently spontaneous pulmonary gangrene or purulent inflammation of the anterior mediastinum or empyema has been found at the autopsy to have been brought about in the way above indicated. These occurrences are fortunately, however, exceptional.

**Treatment.**—The only possible way of treating the large pressure diverticula successfully would be by operation. Perhaps surgery will some day win victories in this domain. In the mean while our efforts are confined to sustaining the patient. If he can not swallow, we must try to feed him through a tube. As long as this is possible, starvation is averted. The best way is to have the patient pass the tube himself. He will find out how best to avoid the sac and reach the stomach. If food can no longer be given in this way, there remain two alternatives: rectal feeding (*vide infra*), or making a gastric fistula. As to the latter, there has been thus far very little practical experience, because cases are so rare.

The traction diverticula admit of no special treatment. If the events above mentioned occur, we must endeavor to meet the indications of the individual case.

## CHAPTER III.

## STENOSIS OF THE ŒSOPHAGUS.

**Etiology and Pathology.**—Contractions of the œsophagus occur with such relatively great frequency that they are the most important of all its disorders. They originate in various ways. By far the commonest cause is ring-shaped carcinoma of the tube. The new growth in the mucous membrane encroaches more and more upon the lumen of the œsophagus, until finally it fills it. Carcinoma will be discussed at length in the next chapter. We shall here confine our attention to its purely mechanical action in causing stenosis.

Œsophageal tumors other than cancer are very rare. Fibrous pedunculated polypi have been observed a few times. They usually originate in the lowest portion of the anterior wall of the pharynx, hanging down into the œsophagus, which they may thus obstruct.

A second cause of stenosis is the contraction of cicatrices of the œsophageal wall. The most frequent occasion for this is the extensive ulceration caused by caustic poisons, such as concentrated acids or alkalies. If the victim escapes a speedy death, he is almost certain to have extensive scars formed in the wall of the œsophagus. These scars radiate irregularly in all directions, and, contracting, may almost completely close the tube.

Ulcers from other causes, resulting in stenosis due to the scars they leave, are among the greatest rarities. Syphilis has been the well-established cause in some instances, and Quincke has described a few cases where there were ulcers at the lower end of the œsophagus analogous to the round ulcer of the stomach, or "ulcer due to digestion" (*vide infra*). These ulcers also may eventually produce cicatricial stenosis.

A third and rare cause of stenosis of the œsophagus is compression from tumors external to it. Such swellings may originate in the thyroid gland, or in the lymph-glands of the neck or the anterior mediastinum; or the swelling may be due to a vertebral abscess or an aortic aneurism. This form of stenosis is seldom extreme, for the portion of the tube pressed upon is usually limited.

Next on the list after stenosis due to compression is usually placed what is called intermittent dysphagia (*dysphagia lusoria*). This term is applied to the difficulty in swallowing which is said to be caused by an anomaly in the course of the right subclavian artery. The artery is given off as the last branch from the arch of the aorta, and runs toward the right side just behind or just in front of the œsophagus. It seems, however, *a priori* improbable that the feeble pressure of this vessel as it pulsates should impede deglutition; nor has it yet been proved to do so. It would be more natural to believe, what was indeed the original explanation of the phenomenon, that a large morsel of food passing down the œsophagus compresses the vessel and thus excites uneasiness and palpitation.

Stenosis due to foreign bodies belongs to surgery. It need not be said that the clinical symptoms differ greatly in different cases. Not only the obstruction, but also a possible laceration and consequent inflammation are to be considered. Occasionally thrush has been abundant enough to cause pronounced symptoms of stenosis.

Above the point of stenosis, no matter how the condition arose, if only it is well developed and has lasted a certain length of time, the circular fibers of the muscular coat are more or less hypertrophied. This hypertrophy is due to the increased force required to propel the ingesta downward. In many cases the tube is also diffusely dilated above the stenosis.

**Symptoms.**—The effect of every œsophageal stenosis is to render deglutition

difficult. If the case is a mild one, the patient experiences nothing more than a moderate pressure in the oesophagus upon swallowing. He feels that the morsel is longer than usual in reaching the stomach. Very soon he notices that solid food and large morsels can be swallowed only with difficulty. Accordingly, he is gradually led to confine himself to a liquid diet, takes only small mouthfuls, and always washing down any solid food with a swallow or two of liquid. The narrower the stenosis, the more he is troubled. Finally, even liquids can be taken only slowly and in sips.

It must not be thought that the dysphagia just described is due exclusively to the mechanical obstruction of the lumen. Sometimes a patient is almost entirely unable to take nourishment, and yet at the autopsy no adequate mechanical obstruction is found. The dysphagia must therefore be due to some lesion of the muscular coat of the oesophagus. The impaired contractility of the muscular coat at the affected spot is always a potent factor in impeding deglutition.

As soon as the dysphagia has become considerable there is usually regurgitation of food. At first only a portion of the food comes up, but at last all of it. If the tube has become dilated above the stenosis, food may collect for some hours, and then be regurgitated, mixed with an abundance of very tenacious mucus. We saw a case of this kind where the patient could fill the sac above the stricture with quite a large amount of fluid without a drop reaching the stomach. If he bent his head sharply forward, the collected fluid would run out again through his mouth. It was not until the pouch was completely filled that a small amount of liquid would trickle through the stenosis into the stomach.

Although the dysphagic symptoms above described generally imply oesophageal stenosis, the diagnosis can not be really established without using a sound. Upon introducing this, it is usually easy to detect the obstacle, which may either allow the instrument to pass, with a noticeable jerk, or else prevent its further progress. By measuring the length of the portion introduced before the stenosis is reached we can learn its position. On the average, the entire distance from the teeth to the cardiac sphincter is in adults sixteen inches (40 cm.); from the teeth to the beginning of the oesophagus, six inches (15 cm.); and consequently the length of the latter is about ten inches (25 cm.). If we succeed in passing a smaller sound through the stricture, the feeling as we move it back and forth will give us some idea of the length of the stenosis, or will detect the existence of several lying one below the other, etc. If the end of the sound can be moved about very freely above the stenosis, we may conclude that the tube is dilated there.

Hamburger has employed auscultation of the oesophagus for diagnostic purposes. If we listen behind, to the left of the upper dorsal vertebræ during deglutition, we hear a gurgling sound, due to the act of swallowing, extending down the tube to the stenosis, but no farther. Then come all sorts of sounds, some of them caused by the fluid trickling slowly through the narrow part, and some caused by regurgitation. In general, the results obtained by auscultation are rather variable and uncertain.

Having established the fact of the existence of a stenosis, we have next to determine its nature, which is our chief guide to prognosis and treatment. In certain instances the history of the case gives us the needed information. The diagnosis of cicatricial stricture can hardly be made unless the patient himself tells us of being burned or injured by caustic poisons. The previous history is likewise of great importance if the stenosis be due to foreign bodies or to syphilis. If no decisive etiological factor can be elicited, we must carefully examine the neck and thorax, with regard to the possible existence of a swelling compressing the oesophagus. In cases where an aortic aneurism has acted in this way, a rhythmical

movement has sometimes been communicated to the free end of a sound introduced as far as the stenosis. If the physical examination does not reveal a compressing tumor, and particularly if the stenosis has developed gradually and in an elderly person, we are almost compelled to assume that there is cancer of the œsophagus. This is, after all, by far the most frequent cause of œsophageal stricture. If the new growth has ulcerated, a little portion of it may adhere to the end of the probe, and, on microscopic examination, render our diagnosis of carcinoma certain.

The prevailing characteristic in stenosis of the œsophagus is inanition, increasing as the dysphagia increases. The patient gets to be very much emaciated, and so feeble that he can not leave his bed. The temperature is subnormal; for weeks it keeps at 95° to 97° (35°-36° C.). The pulse grows very small and slow, being 40 to 60 per minute. The heart-sounds are soft. Respiration is superficial and slow; and toward the close of life short pauses occur after expiration, before inspiration begins. The stomach and intestines are so empty that the abdomen is very concave, while the abdominal walls usually feel tense and resistant. In all cases where the nature of the stenosis precludes the possibility of cure or improvement, death results from increasing exhaustion, the lamp of life gradually flickering out.

**Prognosis and Treatment.**—In prognosis the main factor is of course the nature of the stenosis. If it is due to foreign bodies or to cicatrices, it may be completely cured. In stenosis from other causes it is often possible to produce considerable improvement, at least temporarily. The final result must be confessed to be usually unfavorable, as we should expect from the nature of the original trouble.

The treatment is chiefly mechanical. We shall not speak of operations for the removal of new growths, etc. What we do refer to is a methodical and gradual dilatation of the stricture. Its results are sometimes brilliant, particularly in cicatricial stenosis. Other varieties, like the stenosis from cancer, may sometimes undergo considerable though but temporary improvement with this treatment.

The best instrument to employ is the flexible, so-called English, œsophageal bougie. It is made in all sizes. If the stenosis is very narrow indeed, we may have to resort to catgut at first. Whalebone bougies, with olive-shaped ivory tips of various sizes to screw on the end, are also good, except that, being stiffer, there is more danger in using them. For introduction of the bougie, the patient should be seated, with the head slightly extended backward. The first two fingers of the left hand are introduced into the throat and guide the instrument, previously well oiled, over the back of the tongue and the epiglottis into the œsophagus. Of course, no violence must be used. Otherwise a perforation might occur if there were a soft, broken-down cancer, or an aortic aneurism. However, such a misfortune is very exceptional.

The use of the bougie is almost invariably beneficial if the stricture can be passed. The patient generally finds that he can swallow easier than before, and will himself request a repetition of the performance. If the patient is an intelligent person, it is advisable to have him introduce the bougie himself. Patients often acquire even greater skill with it than the physician has. The bougie should be passed regularly once a day, or, at most, twice daily; and in favorable cases we shall be able gradually to increase the size. If so, the symptoms speedily abate, and, with the increased ingestion of food, the patient gains flesh very fast.

If the stenosis is extreme, and, although it admits the bougie, does not allow of sufficient nourishment, we must pass a tube into the stomach through which to introduce liquid food. Milk is the best food to choose. Raw eggs, sugar, wine, etc., may be mixed with it. The various infant's foods and Hartenstein's "legu-

minose" are also excellent. Their consistence is favorable for the purpose, and they supply a considerable amount of nourishment in a small bulk.

If this means also fails us, two alternatives are left, unless we are to resign our patient to death by starvation: (1) operative interference, œsophagotomy if the stenosis is high up, otherwise gastrostomy; (2) rectal feeding.

For information about the operations we must refer to surgical literature. As to feeding *per rectum*, its results are never brilliant. It is indeed probable that life may be by this means somewhat prolonged, but not indefinitely. But the moral effect is very valuable, when the patient could otherwise receive no nourishment whatever. The sufferer feels that something is being done to avert absolute starvation.

The simplest materials for the nutrient enemata are milk, eggs, and wine; to which we may add pepsine and pancreatine in the hope of promoting absorption. Leube's pancreatic meat emulsion is still better, although more troublesome in its preparation. Leube's directions are as follows: About five ounces (150 grm.) of meat, cut very thin and then minced finely, and about two ounces (50 grm.) of minced pancreas (from the calf) free from fat, are to be stirred with about three ounces (100 grm.) of lukewarm water until the mixture has the consistence of gruel. Before it is injected, the rectum should be cleansed by an enema of plain water. One such enema is to be given daily.

#### CHAPTER IV.

#### CANCER OF THE ŒSOPHAGUS.

**Ætiology and Pathology.**—Cancer is the most important and most frequent affection of the œsophagus. We have already mentioned in the preceding chapter that often stenosis is the result of carcinoma in the œsophageal walls.

Little is known about the ætiology. It has been often maintained that mechanical, chemical, or thermic irritation of the mucous membrane may result in the development of cancer; but this is not certain. It receives some support from the remarkably frequent occurrence of œsophageal cancer in hard drinkers. Now and then the patient himself will allege a perfectly definite cause for his disease, such as the lodging of a foreign body, or the swallowing of a very large or very hot morsel. Still it is hardly possible in any particular case to decide how much value such statements have. It has been maintained that the carcinoma sometimes develops in the scars of old ulcers. This is of interest when we recall the similar fact in regard to gastric carcinoma (*vide infra*).

(Œsophageal cancer follows the general rule in being most frequent in elderly people—somewhere between forty and sixty years of age. The male sex is decidedly more often attacked than the female.

As we might expect from the histological character of the epithelium lining the œsophagus, primary cancer here is invariably composed of pavement cells. The new growth may be either hard, firm, and fibrous, or it may be soft, succulent, and but scantily supplied with connective tissue. The first variety corresponds to the "scirrhus" of older writers, and the second to "medullary" cancer. Usually the new formation encircles the entire tube like a ring, extending three to ten centimetres longitudinally. Exceptionally a still larger portion of the œsophagus is involved, sometimes almost all the mucous membrane. The tumor is usually seated in the lower and middle thirds of the œsophagus, being much rarer above.

**Symptoms and Complications.**—In the great majority of cases the symptoms

usual, so as to suggest the name of a desquamative catarrh. It is in only a few cases that the scanty mucous glands become swollen and look like papules upon the surface of the membrane; this form is called follicular catarrh. In limited areas the desquamation may be complete, giving rise to small catarrhal erosions. Likewise, the swollen follicles may break down into small follicular ulcers.

In chronic catarrh there is a moderate increase in the secretion of mucus, and a marked thickening of the epithelium. In very protracted cases actual papillomata may finally be formed. In some cases ulcers are seen.

Croupous and diphtheritic inflammations of the œsophagus are very rare. We have already said that the specific pharyngeal diphtheria frequently extends into the larynx, but only exceptionally into the gullet. Still, we have ourselves seen in a child a stricture in the upper third of the œsophagus, which was said to have been a result of a severe attack of diphtheria. Isolated cases of diphtheritic œsophagitis have also been seen in connection with severe infectious diseases, such as typhus, typhoid, small-pox, cholera, pyæmia, and pulmonary tuberculosis, as well as in the course of Bright's disease and cancer. In variola it is not unusual for pocks to appear upon the œsophageal mucous membrane.

A purulent, phlegmonous œsophagitis now and then attacks the submucous layer. It may be either diffuse or circumscribed. The mucous membrane is dissected up from the muscular layer by the pus, and pushed inward, so as to diminish the lumen of the œsophagus more or less. Most of the cases end by the discharge of matter into the tube, when complete recovery may ensue. If the mucous membrane, however, has been extensively undermined, Zenker states that a fissure-like cavity may be left, even after healing has taken place. Its walls grow smooth, and finally acquire a layer of fresh epithelium.

Purulent œsophagitis is caused either by the presence of foreign bodies in the œsophagus, or by purulent inflammation in neighboring parts, as in glandular abscess, vertebral abscess, or laryngeal perichondritis. It has now and then resulted from the action of concentrated acids and the like upon the mucous membrane.

The action of corrosive poisons (corrosive œsophagitis) is to cause necrosis of the tissues, which in its turn produces inflammation. The inner surface of the œsophagus is converted into a rotten, hæmorrhagic, sloughing mass, of a dirty gray or almost black color. The muscular layer itself may be partly destroyed. If death does not occur speedily, the necrosed portions come away, leaving extensive purulent ulcers behind. These, if they heal at all, cause large cicatrices and stenosis.

**Symptoms.**—The milder cases, as we have stated, produce almost no distinctive symptoms. Possibly there may be pain along the œsophagus, or at some one point in it, during deglutition. In a more severe case the pain may be great; but the other symptoms are usually too grave for this to excite special attention. Laborious deglutition, and the feeling as if the food were inclined to stick in the throat, result from implication of the muscular layer. A diagnosis of the particular form of œsophagitis is attainable only when the ætiology guides us to it.

Treatment must be purely symptomatic. No solid food should be taken. The pain is to be allayed by bits of ice, or by morphine.

## CHAPTER II.

## DILATATION OF THE ŒSOPHAGUS.

## 1. Diffuse Dilatation.

DIFFUSE, spindle-shaped dilatation of the œsophagus is observed as a result of stricture of the cardiac orifice. At first the muscular coat hypertrophies as the orifice contracts, and is able to overcome the obstruction, so that there is no dilatation; but as soon as the muscles are paralyzed, and food collects behind the stricture, the dilatation begins and keeps on increasing. The ectasis is greatest at the lower end of the tube, as is natural from its mode of origin, and gradually diminishes upward.

There have been a very few well-substantiated instances of this diffuse spindle-shaped dilatation, without any demonstrable stenosis of the cardiac orifice. Their cause is unknown. Sometimes the walls of the œsophagus may have been rendered more yielding and less contractile by a precedent inflammation or other disorder. In other cases, some chance bend or distortion of the lower end of the œsophagus may have produced a mechanical obstruction. In some cases the exciting cause is said to be a blow on the chest, or the lifting of a heavy weight.

The symptom of this condition, when well developed, is a chronic difficulty in deglutition, lasting perhaps for years. The patient himself feels that most of the food he eats does not reach the stomach, but lodges higher up. Usually the food is soon afterward vomited, or rather gulped up. When there is stenosis of the cardiac orifice, the explanation of these symptoms is easy. It is much harder to explain the almost equal dysphagia where there is dilatation without stenosis. Sometimes a localized bulging of the wall causes the food to collect in that spot, and thus to obstruct the lumen. As is to be expected, the partial or complete hindrance to the ingestion of food results in marasmus.

If there is stenosis, it can easily be detected with the œsophageal sound, and all the symptoms thus explained. In the rare cases, however, of diffuse dilatation without stenosis, the use of the sound does not give us so much information. If the instrument passes readily into the stomach, we may safely exclude stricture; but, in one case of our own, we made an erroneous diagnosis of a diverticulum, because the sound sometimes glided readily into the stomach, and sometimes could not be passed. A pocket must have been formed at the lower end of the dilated tube, in which the sound caught.

The treatment is directed chiefly to the satisfactory nourishment of the patient; for the œsophageal trouble itself is dangerous only as it prevents the taking of food and leads to starvation. We do not speak of the initial lesion, if there be one, which causes the dilatation. If nourishment can be given through a stomach-tube, the patient almost invariably shows a rapid improvement, which lasts as long as the artificial feeding can be kept up. If, however, any cause prevents the introduction of the tube, we must resort either to nutrient enemata (*vide infra*)—and these will not support the system indefinitely—or we must make a gastric fistula. In the latter case the prognosis depends on the success of the operation and the nature of the original lesion.

## 2. Diverticula.

**Ætiology and Pathology.**—Circumscribed pouches in the wall of the œsophagus are termed diverticula. They are divided into two essentially distinct varieties, according to their mode of origin. Zenker has given them the names of pressure and traction diverticula.

The diverticulum due to pressure is extremely rare. It is caused by pressure upon the mucous membrane from within, by which some abnormally weak spot is forced outward. All cases that have been carefully examined thus far have shown that, histologically, the wall of the diverticulum is not the distended but otherwise unchanged wall of the œsophagus, but is composed exclusively of the mucous membrane and the thickened submucous coat. We are therefore obliged to suppose that the mucous membrane is pushed out like a hernia through some gap in the muscular coat. It is only about the neck of the diverticulum that any muscular fibers are found.

The original factor, therefore, in the occurrence of a pressure diverticulum is apparently to be sought in some circumscribed lesion of the muscular coat. As a result of several observations, it is established that a foreign body, sticking in the throat, may separate some of the muscular fibers and push the mucous membrane through the gap thus formed. Or a severe injury leads to a trifling rupture of the muscular coat, and then the food, as it is being swallowed, presses out the mucous membrane at this weakened spot. There are still many other cases where the true origin of the diverticulum remains obscure.

As soon, however, as the formation of the pouch has once begun, there are many influences to make it grow larger. Each successive bit of food, as it glides by, presses upon this yielding and inelastic spot. Gradually a little sac is formed, in which bits of food lodge. These exercise a constant pressure upon the walls of the pouch, and by their weight drag it bodily downward. The larger the pouch, the more it holds, and consequently the more it grows. Thus a pressure diverticulum of the smallest size originally may gradually attain to a diameter of four inches or more. The general shape of the diverticulum may approach the hemispherical, or it may be more cylindrical or pear-shaped.

It is remarkable that, with very rare exceptions, these pressure diverticula are always situated at the beginning of the œsophagus, or rather between it and the pharynx, and almost invariably affect the posterior wall. The pouch hangs, therefore, in front of the spinal column. It pushes out through the lowest fibers of the inferior constrictor of the pharynx; and the feebleness of this muscle is apparently a potent factor in determining the precise point of origin.

The cases thus far seen have been almost all in men, and at a rather advanced age. A few cases have occurred in children.

Traction diverticula are much more common, but in most instances have little interest except for the pathologist. They are not infrequently found unexpectedly at the autopsy. Rokitsansky, and later Zenker, have given explanations of their occurrence: some tissue, which has formed adhesions to the œsophagus, contracts and gradually pulls out the œsophageal wall in the shape of a funnel. Bronchial glands are apt to be the seat of the contractile change. These glands are situated near the bifurcation of the trachea, and accordingly the traction diverticula occur oftenest at this level. There may be two or three in one subject. They are rarely over a third of an inch in depth. From within, the mucous membrane, much wrinkled transversely, is seen to be drawn toward the apex of the diverticulum. The wall of the latter consists either of the mucous membrane alone, bulging out like a hernia, or of the mucous membrane covered by the muscular layer. Inasmuch as children quite often suffer from suppuration and caseation of bronchial glands, with subsequent shrinkage, we see why traction diverticula are frequent in children.

**Clinical History.**—The large pressure diverticula always cause grave symptoms, for they obstruct more and more each day the passage of food. At first there is scarcely any disturbance. Gradually, however, deglutition is impeded. A portion of the food lodges in the pouch, and is either wholly or in part regurgitated,

though perhaps not immediately. Decomposition is apt to take place in the contents of the diverticulum, giving rise to foulness of the breath and to nausea. The danger reaches its climax when the distended sac presses sidewise upon the œsophagus and closes its lumen, so that no food reaches the stomach. After protracted strangling and vomiting, the material may be in part ejected, and the patient enabled once more to swallow.

Of course the symptoms in individual cases depend upon the mechanical conditions present, and may vary greatly. Patients contrive all sorts of manipulations, by which they manage to get at least some portion of their food down. Such individuals may maintain a tolerable degree of nutrition for years, although they scarcely ever are in a normal condition. But at last some cause or other renders the amount of food ingested inadequate; whereupon a rapidly progressive marasmus sets in, and the patient will inevitably starve to death unless some relief is afforded.

The most valuable objective evidence in these cases is gained by the use of the œsophageal sound. If the sound enters the sac, its passage is impeded. If it happens to slip by the mouth of the diverticulum, it glides readily into the stomach. This varying result may sometimes be obtained at one sitting by repeated trials, and is of the greatest importance in making the diagnosis.

In some instances where the sac was large, a tumor in the neck has been observed at one side of the trachea, appearing after eating and disappearing when the sac emptied itself. Symptoms due to compression of the recurrent and phrenic nerves and of the blood-vessels have been noticed in some cases.

Auscultation of the œsophagus during the act of swallowing has been practiced, and, of late, attempts have been made to examine it with a speculum. Whether these methods of investigation will prove valuable for diagnosing diverticula, experience must determine.

The traction diverticula are usually of no clinical importance. They do not affect deglutition at all, and their size is too limited to permit any great accumulation of food in them. There is but one way in which they are dangerous: the apex of the funnel may undergo ulceration and perforation. A foreign body, like some bit of food, produces necrosis of the wall, by what is probably at first a purely mechanical irritation. The tissue ulcerates; and then the inflammation may gradually progress till it causes a severe and usually fatal illness. The most frequent event is perforation into a bronchus, followed by the aspiration of food and pulmonary gangrene. Or the perforation takes place into the pleural cavity, exciting an ichorous empyema. In other cases the pericardium or a large vein has been perforated. Many a case of apparently spontaneous pulmonary gangrene or purulent inflammation of the anterior mediastinum or empyema has been found at the autopsy to have been brought about in the way above indicated. These occurrences are fortunately, however, exceptional.

**Treatment.**—The only possible way of treating the large pressure diverticula successfully would be by operation. Perhaps surgery will some day win victories in this domain. In the mean while our efforts are confined to sustaining the patient. If he can not swallow, we must try to feed him through a tube. As long as this is possible, starvation is averted. The best way is to have the patient pass the tube himself. He will find out how best to avoid the sac and reach the stomach. If food can no longer be given in this way, there remain two alternatives: rectal feeding (*vide infra*), or making a gastric fistula. As to the latter, there has been thus far very little practical experience, because cases are so rare.

The traction diverticula admit of no special treatment. If the events above mentioned occur, we must endeavor to meet the indications of the individual case.

given. We may order as much bicarbonate of soda or as much magnesia as will rest on the point of a pen-knife. The so-called stomachics and bitters are also often prescribed, such as compound tincture of gentian or tincture of rhubarb. If the vomiting is obstinate, the best remedies are bits of ice, sips of cold seltzer water, or small doses of opium. If the bowels are constipated, Carlsbad salts, Hunyadi water, or rhubarb may be given.

## CHAPTER II.

### CHRONIC GASTRIC CATARRH.

(*Chronic Gastritis. Chronic Dyspepsia.*)

**Ætiology.**—The same injurious influences which produce acute gastric catarrh if frequently recurring, excite the chronic form of the disease. The most potent causes are improper diet and the improper use of alcohol. Individual predisposition is important in this as well as in the acute disease. Sometimes it even seems to be a matter of inheritance. It is not a rare thing to find that a large number of the members of a family have a "weak stomach."

Chronic gastric catarrh is not always a primary affection. It may be secondary to some other disease. All diseases which result in passive hyperæmia of the portal system, such as cirrhosis of the liver or thrombosis of the portal vein, are not infrequently followed by gastric catarrh; and when the disease occurs in persons afflicted with chronic cardiac or pulmonary disease, it is to be regarded as in part due to stasis.

**Pathology.**—The macroscopic changes in the gastric mucous membrane are in most cases very slight. Usually it is coated with a layer of tough, grayish-white mucus, in which is suspended a greater or less amount of detached epithelium. The membrane is red, unless rendered gray by excessive pigmentation. The changes are almost always most extensive in the pyloric region.

If the catarrh is of long duration, there may be still further changes. The mucous membrane often seems smooth and atrophied. The glands are narrower and shorter than normal, and the connective tissue between them is increased in amount. Other cases present hyperplasia of the mucous membrane. The internal surface of the stomach is thickened and mammillated. The hyperplasia in these cases affects chiefly the tubes of the glands in the mucous membrane, although the submucous layer may also be considerably thickened.

**Symptoms.**—The symptoms of disturbed gastric digestion, or dyspepsia, to be observed in all sufferers from chronic gastric catarrh, are referable to the following functional anomalies:

The secretion of the gastric juice depends upon the maintenance of the circulation of the blood in the gastric mucous membrane. This is merely in accordance with a general rule. It is easy, therefore, to comprehend that any inflammation, disturbing as it does the circulation of the blood, must modify the gastric secretions. We may also assume that a deficiency in the secretion of the gastric juice is the chief factor in producing the dyspepsia which accompanies both the primary and inflammatory catarrh and that resulting from venous stasis. The possible diminution in the production of pepsine is probably not of great importance in this connection; for, like any other ferment, a very small amount of it would prove efficient under favorable circumstances. What seems of more importance is the diminished proportion of hydrochloric acid in the gastric juice of patients with chronic gastric catarrh—a condition which has been repeatedly proved to exist. The pro-

cesses of digestion are thereby not a little lowered and impeded. It is self-evident that in cases where there is actual atrophy of the mucous membrane and of the glands in particular, the normal processes of gastric secretion may be still more seriously impaired.

A further unfavorable result of the imperfect digestion dependent on the lack of hydrochloric acid is that the undigested food is very apt to undergo abnormal fermentation and decomposition. These fermentative processes give rise to lactic, butyric, and acetic acids, and to alcohol. The direct cause of their production is that the ferment-producing spores are not destroyed by the gastric juice, as they would be under normal conditions. On the contrary, they find in the food stagnating within the stomach the most favorable conditions for the development of their activity. These products of abnormal fermentation in their turn irritate the gastric mucous membrane and prolong the catarrh.

Another factor contributes to the disturbance of the normal digestive processes, namely, the excessive secretion of mucus. As mucus has an alkaline reaction, its presence neutralizes a portion of the acid in the gastric juice and lessens the potency of the latter. The mucus also does harm in a purely mechanical way. It envelops all the ingesta, and thus to no small degree prevents the gastric juice from reaching them. Morsels completely covered with mucus can remain for quite a long time in the stomach without being digested.

A very great importance attaches to the motor disturbances which the stomach suffers in chronic catarrh. The normal peristalsis is of course an essential factor in the process of digestion. It is its function to bring all portions of the contents of the stomach successively into adequate contact with the mucous membrane. Thus alone is the uniform digestion of the entire mass rendered possible; and, as physiology has taught us, the gastric secretions are continually being stimulated by the contact of the still undigested food with the lining membrane. Lastly, it is the peristalsis again which pushes on the already digested food into the duodenum, and thereby prevents the useless accumulation of matter within the stomach.

Now, gastric peristalsis is undoubtedly much impaired in catarrh. One reason for this is the actual harm done the muscular coat. Every decided inflammation renders the muscular layer cedematous, and thus impedes its activity. In all cases where food accumulates in undue amount in the stomach, the muscular coat is gradually so stretched as to become still more incapacitated for its proper functions. A factor which is perhaps of still greater importance than these lesions is the diminished vigor of the normal excitants of the peristaltic movements. We learn from physiology that the chief part in arousing peristalsis is played by the normally constituted gastric juice, and more especially by the acid therein contained. It follows that all influences which modify the amount or composition of the gastric juice must have the remote effect of diminishing the gastric peristalsis. The resulting evils can be inferred from what has been already stated. Digestion is impaired, and abnormal decomposition promoted; and each effect becomes in turn a cause of further derangement—a condition of things which we are constantly meeting in the pathology of digestion.

It remains to be stated that absorption is impeded in chronic gastric catarrh. It has been shown in Ludwig's physiological laboratory, in Leipsic, that no inconsiderable portion of the peptones manufactured in the stomach are absorbed by the blood-vessels in its walls. Now, as the circulation is disturbed by the inflammation, we should expect the absorption of peptones to be thereby diminished. The peptones remaining in solution within the stomach and not absorbed have been shown by experiment to disturb and delay the transformation of fresh albuminous substances into peptones. The diminished peristaltic action also tends to prolong the time during which the peptones remain in the stomach; and numer-

ous observations teach that normal peristalsis has a direct influence in promoting absorption, so that, if it be diminished, absorption is checked.

We have therefore a whole series of factors, all of which contribute to disturb the normal processes of digestion. We have discussed them at some length, because they serve to explain not only the digestive symptoms of chronic gastric catarrh, but those of almost all the other gastric diseases.

If we now proceed to the symptoms which lead us to a diagnosis of dyspepsia or chronic gastric catarrh, we find first anorexia. This symptom is common to all gastric disorders. There is sometimes a moderate appetite, but it is soon changed to a feeling of repletion upon the ingestion of even a slight amount of food. In other cases there is actual dislike for any form of nourishment; the patient eats little, and prefers highly spiced, piquant dishes. There is often a persistent bitter, flat, or otherwise abnormal and disagreeable taste in the mouth.

Subjective sensations in the region of the stomach are rarely entirely absent. As a rule, there is a feeling of fullness or pressure and of dull pain. These troubles may either be constant, or occur after meals.

The eructation of gas is a very frequent and annoying symptom. Often a sour liquid comes up with the gas ("sour stomach"). The gas is a mixture of atmospheric air and the abnormal gaseous products of the decomposition which takes place in the stomach. Hydrogen, carbonic dioxide, and occasionally inflammable gases, such as marsh gas, have been detected. The sour masses regurgitated irritate the oesophagus, and give rise to a sharp, burning sensation, known as "heart-burn."

In many instances the feeling of nausea is superseded by actual vomiting. This almost always takes place either directly after eating or an hour or two later. The vomitus consists mainly of undigested food, usually mixed with a large amount of mucus. The chemical reaction may be either neutral or strongly acid.

FIG. 34.—a, *Sarcina ventriculi*. b, Yeast-cells.

If acid, however, it is often not made so by hydrochloric acid, but by the acetic, lactic, or fatty acids generated by the abnormal fermentation going on within the stomach. That the contents of the stomach have an acid reaction is no proof that the gastric juice has peptonizing properties, for none of these other acids have nearly so much efficiency in promoting digestion as has hydrochloric acid. They may even at times check the process. A small amount of blood may be mixed with the matter vomited, but need not excite apprehension. Microscopic examination reveals little that is characteristic. The cells of the yeast fungus are frequently found, and also the *sarcina ventriculi* (see Fig. 34). We may add that this latter has apparently no connection with the abnormal processes of fermentation.

A peculiar kind of vomiting is extremely frequent in the chronic gastric catarrh of drunkards. We refer to the well-known morning vomiting of a watery fluid, which is usually alkaline in reaction, and apparently consists at least in part of saliva that has been swallowed. (*Vide* also page 357.)

The physical examination shows malnutrition (*vide infra*), but not much that is distinctive of the disease. The center of the tongue is often coated, while its point and edges are red. Considerable salivation not infrequently exists.

The epigastrium seems in many cases unchanged. Sometimes the stomach is distended, and somewhat tender on pressure. On palpation, a splashing can sometimes be both heard and felt. Its presence usually indicates dilatation of the stomach (*q. v.*).

## EXAMINATION OF THE CONTENTS OF THE STOMACH BY MEANS OF THE STOMACH-TUBE.

The examination of the contents of the stomach with the aid of the stomach-tube is much more important than the mere external examination of the stomach, which usually affords little information. This newer method of research was introduced mainly by Leube, and by its means we are able to learn about many of the processes of digestion, and to obtain a somewhat clearer insight into the especial forms of digestive disturbance which may be present. The use of the stomach-tube for this purpose has indeed certain inconveniences for the patient, and therefore it will not, of course, be used immediately in every case. If, however, we have to deal with any obstinate disorder of the stomach, investigation by means of the tube is the more desirable because we may thus obtain data valuable not only from a diagnostic but also from a therapeutic point of view.

The first question which can be determined with the aid of the stomach-tube relates to the time occupied in digestion, or, in other words, to the motor power of the stomach. The best tube to use is the soft catheter of Nélaton, supplied at its lower end with sufficiently wide openings. Numerous experiments on healthy human beings have shown that under ordinary circumstances gastric digestion is ended in six or seven hours at the latest, so that we should find the healthy stomach completely empty six or seven hours after the last meal. Indeed, frequently this is the case much earlier, say three or four hours after a meal. The investigation of this point in disease of the stomach is usually carried out in the following way: The patient is given, either in the morning fasting or at noon, a so-called test-meal; this consists either of flesh, such as minced beef-steak, with a roll, or merely of a roll with some tea. Six or seven hours after this meal the stomach is rinsed out with lukewarm water. In normal digestion the rinse-water is almost perfectly clear, and contains at most a few small bits of mucus and the like, while in dyspepsia there are still present in the stomach numerous remnants of the ingesta. This latter condition demonstrates with certainty the presence of disorders of digestion; while the sufficiently rapid emptying of the stomach is in most cases a sign of normal digestion, although it may sometimes exist despite some few deviations from perfect health.

We must therefore endeavor to make further investigation as to the quality of the gastric juice and the digestive power of the stomach, and for this purpose also the stomach-tube is indispensable. The result of attempts to obtain a perfectly pure and undiluted gastric juice has, to be sure, thus far been unsatisfactory; still, we are able to get most of the reactions in a satisfactory way from the total gastric contents—that is, from the gastric juice mingled with portions of food. For this purpose we must, of course, draw out the gastric contents at a time when the secretion of the gastric juice has reached its highest point, and, accordingly, the tube is introduced about an hour or an hour and a half after the test-meal. By coughing and pressing the patient is usually able to squeeze out a sufficient amount of the gastric contents through the tube, and this by filtration is separated from the remnants of the food. The filtrate thus obtained may now be tested in various ways. If, however, we can obtain none of the contents of the stomach by mere expression, it is necessary to gain our result by pouring some fluid into the stomach and siphonage. For the investigation of the quality of the gastric juice it is in general preferable to give the so-called test-breakfast, consisting of a roll and tea, because if we give a larger test-meal the secreted hydrochloric acid is at once and completely combined with the abundant nitrogenous substances present. In that case the test for free hydrochloric acid proves negative, even when the stomach has secreted hydrochloric acid in abundance.

The investigation of the gastric juice thus obtained relates, first, to its richness in acids, and in particular free hydrochloric acid, and, secondly, to its digestive power.

The digestive power of the gastric juice is tested in the following way: A thin shaving of coagulated egg albumen is allowed to stand in the gastric juice for sixty to ninety minutes. If the gastric juice possesses normal efficiency, the albumen will be completely dissolved at the expiration of this time. Under pathological conditions the gastric juice requires a much longer time for this, or it may not digest the albumen at all until a few drops of hydrochloric acid are added.

Testing the gastric juice in relation to the acids it contains has become, as the result of numerous investigations, a matter of great importance during the last few years. In the first place, we must determine whether the juice contains any free acid at all or not. This is best done by means of a solution of tropæolin. Even slight amounts of acid change the yellow color of tropæolin to red. Red Congo-paper is also to be recommended for demonstrating free acids. This takes on an evident blue coloration upon the application of a drop of acid gastric contents. Both reactions take place only if free acids are present. They are not produced by acid salts.

If the gastric juice contains free acid, the next question is whether this free acid is hydrochloric or lactic. Hydrochloric acid is certainly the acid which is by far more important and absolutely necessary to digestion, while lactic acid is probably entirely dependent for its creation upon the digestion of the starches in the stomach. In the case of normal digestion lactic acid alone is found during the first half-hour, the amylolytic stage of gastric digestion. Then the hydrochloric acid begins to appear along with the lactic acid. The latter grows less and less abundant, and at the end of an hour there is usually found hydrochloric acid alone without any lactic acid. The most certain and best means for the demonstration of free hydrochloric acid is the phloroglucin-vanillin test of Günzburg. The solution is composed as follows: Phloroglucin 2, vanillin 1, absolute alcohol 30 parts. A few drops of this solution are mixed in a porcelain evaporating dish with a few drops of the gastric juice which is to be examined, and warmed over a flame. If there be free hydrochloric acid present there at once appears at the edge of the heated liquid a beautiful red border. The test is very easy to carry out, and extremely sensitive. The second reaction for free hydrochloric acid is with methyl-violet. Its solution has a violet color, which changes to blue upon the addition of a small amount of hydrochloric acid, while lactic acid does not produce this change in color. For the direct demonstration of lactic acid, on the other hand, we may use Uffelmann's chloride of iron and carbolic test. Upon the addition of a drop of liquor ferri perchloridi to a two-per-cent. solution of carbolic acid, there is at once developed a steel-blue color. Upon adding the gastric juice to this mixture the blue color will at once change to yellow, if lactic acid be present.

According to the later investigations of Cahn and Von Mehring, we must add that the failure of the reactions for hydrochloric acid does not authorize us to assert that there is actually a complete absence of hydrochloric acid in the gastric juice. The authors just named have demonstrated hydrochloric acid where the methyl-violet reaction has failed. Nevertheless, the negative result of the test, which, it seems, must be caused by the mixture of foreign matter with the gastric juice, does possess practical importance, inasmuch as the reaction can always be demonstrated if digestion is normal.

If we now return from this digression to the conditions present in chronic gastric catarrh, we find that in this disease digestion is often decidedly delayed and incomplete. The gastric juice usually contains free hydrochloric acid, but the

amount of it is often appreciably diminished. Indeed, there are severe cases of chronic gastric catarrh where the secretion of hydrochloric acid seems to be permanently almost *nil*. This is probably to be explained by the final occurrence of an atrophy of the mucous membrane. The appearance of abnormal organic acids in the gastric contents, such as butyric and acetic acids, points to processes of abnormal fermentation in the stomach.

With regard to those disturbances which are associated with an increased secretion and an abnormally large amount of acid in the gastric juice, see the appendix to this chapter.

Of the other organs, the intestine most frequently suffers in chronic gastric catarrh. The combination of gastric disease and intestinal disease is not infrequent. In almost all cases of chronic gastric catarrh the bowels are irregular. Habitual constipation is the rule, but sometimes there is diarrhoea. If much gas is generated in the stomach, the intestinal canal often becomes implicated, and tympanites and flatulence develop. There may be catarrh of the duodenum leading to jaundice.

The urine is often only feebly acid in reaction, and therefore frequently deposits a large amount of phosphates. The diminished acidity is probably in part a result of the deficient secretion of acid by the stomach, though excessive vomiting (compare the chapter on dilatation) may also have some influence, because of the acid thus lost.

It has been often maintained that eczema and other chronic cutaneous diseases are sometimes referable to gastric catarrh, but the fact has not yet been definitely established.

There is a more evident relation between chronic gastric catarrh and certain nervous derangements. The disease has a notable influence on the spirits. In numerous instances it is accompanied by decided hypochondriasis. There may be other nervous symptoms, such as headache, vertigo, and dullness or listlessness. Vertigo in particular is a familiar concomitant of the disease ("*vertigo a stomacho laeso*"). It is possible that in many cases these symptoms are toxic, resulting from the absorption of the abnormal matters generated within the stomach (*vide supra*, page 373). In the majority of instances, however, they are due to the neurasthenic and hypochondriacal condition of the patient (see the chapter on nervous dyspepsia).

Whenever the catarrh is of any duration and severity, the general nutrition is seriously impaired. The diminished appetite and the imperfect digestion and absorption of what is eaten contribute to produce a gradual and considerable loss of weight. The fatty and muscular tissues atrophy. The skin grows dry and harsh, and usually has a dirty-pale color.

Individual cases differ greatly in the combination of symptoms they present and in their course. The anorexia, gastric oppression, eructations, vomiting, and other important disturbances already mentioned, exhibit the greatest diversity in their intensity and their grouping. In the milder cases, loss of appetite and moderate local uneasiness may be the only symptoms. Frequent vomiting is seen only in the severer cases. The disease often lasts for years, especially if the patient neglects himself. In most cases there are frequent remissions and exacerbations, usually dependent upon external causes.

The disease is not intrinsically fatal, but the general debility consequent upon it may indirectly shorten life.

**Diagnosis.**—The diagnosis is based upon the existence of chronic gastric symptoms unattended by evidence of any more serious lesion, whether of the stomach itself or of some other organ. For example, the possibility of gastric ulcer, cancer, or dilatation is to be considered. This elimination of other diseases is very

important. It is not at all exceptional to meet in practice cases that have been carelessly diagnosticated as chronic gastric catarrh where a more thorough examination or the further progress of the case leads to an entirely different conclusion—chronic pulmonary or cardiac disease, chronic nephritis, or one of the other gastric affections above mentioned. It should therefore be our invariable rule to reach the diagnosis by exclusion, after making a careful and complete physical examination, in order to detect any other possible disease to which the gastric symptoms might be referred. The important differential diagnosis between chronic gastric catarrh and so-called nervous dyspepsia will be discussed hereafter.

**Treatment.**—If the disease seems to be merely symptomatic—the result, for instance, of venous stasis due to chronic cardiac, pulmonary, or hepatic disease—our efforts must, of course, be chiefly directed to the relief of the original trouble.

Treatment of the primary form, on the other hand, must always begin with regulation of the diet. Such vague injunctions as “to be cautious” or “to avoid indigestible articles of food” are useless. The patient must have a perfectly definite bill of fare prescribed for him; nor can any universal one, suitable for all cases, be drawn up. In each individual instance the individual circumstances must be considered. The personal experiences of the patient himself are by no means to be disregarded. One man may be quite unable to digest what is well borne by others, and *vice versa*.

In the first place, certain foods must be utterly forbidden to such patients as do not themselves avoid whatever disagrees with them. All articles must be prohibited which may irritate the mucous membrane, either mechanically or chemically. This includes all the coarser sorts of vegetables or fruits, containing a large proportion of indigestible cellulose; and all dishes that are very sour, strongly salted, or highly spiced. Potatoes, farinaceous food, and all substances mainly composed of hydrocarbons, must also be interdicted; because almost all the abnormal fermentative processes, the evil consequences of which have already been considered, are promoted by the hydrocarbons. Fat is also harmful. It impedes digestion by protecting the contents of the stomach from the action of the gastric juice, in a purely mechanical way; and then, being changed into the fat acids, it causes sour eructations and pyrosis. It is important that all forms of alcohol should be forbidden. Fleischer and others have proved by actual experiment that even small amounts of alcohol prolong and hinder the digestive process. An injunction to abstain totally is usually better obeyed in a severe case than the advice to be very moderate in the use of liquors. The food should neither be very hot nor ice-cold.

In determining what the patient may be allowed to eat, we are to consider, as already mentioned, his own personal experience as well as our more general knowledge. An intelligent patient will often be himself the best judge of what agrees or disagrees with him. The following foods are very easy to digest: Milk, soft-boiled or raw eggs, broths, and certain artificial preparations, chief among which stand the Leube-Rosenthal meat solution and the meat peptones which have been lately put upon the market. The brain and sweetbread of calves are easily digestible; also birds, such as pigeons, chickens, and partridges, and thin shavings of raw meat or raw ham. Gradually we may proceed to somewhat heartier food—veal, game, roast beef, and light farinaceous dishes. The worse the symptoms are in any case, the more strict must we be in regard to diet. For drink, besides water or Seltzer water, very weak tea and non-oleaginous cocoa are good.—Shall we permit coffee? This is often a question of great interest to the patient: it must be answered according to his individual experience. Coarse bread is to be forbidden. Ordinary white bread, toasted, if it seems desirable, may be allowed in moderate amount.

Solid articles of diet must be finely cut up and well chewed before being swallowed. It is sometimes advantageous to take more than three meals a day, each one being proportionally smaller. Other patients relish their food better if the intervals between eating are prolonged.

There are other special indications to be met. As we have already seen, one of the chief factors in maintaining digestive disturbance is the abnormal detention of undigested food in the stomach. If we can only empty the viscus properly, we thereby relieve it of the abnormal processes of decomposition and fermentation, as well as of mucus which may have collected in injurious amount. This indication is best fulfilled by the mechanical treatment of chronic gastric catarrh by means of the stomach-pump. Its results are often brilliant; but rinsing out the stomach is never agreeable to the patient, and the method should not be resorted to except in severe and inveterate cases. The most suitable are those where an examination of the contents of the stomach, made as above described, shows that abnormal fermentative processes are going on, or that the ingesta stagnate in the organ. For further particulars we refer to the chapter on dilatation.

If we now turn to a consideration of the internal remedies used in chronic gastric catarrh, it is possible to decide with regard to their employment in a much more intelligent fashion than heretofore, because we are able in all severer cases to prosecute a more accurate investigation of the digestive process. If the examination of the gastric juice shows a diminution of hydrochloric acid, this may be artificially supplied. We prescribe, thirty to sixty minutes after each meal, ten to fifteen drops of dilute hydrochloric acid in half a glass of water. The benefit to be thus derived must not be overestimated. In appropriate cases, however, its influence is favorable. One may also make a trial of pepsin—*pepsini Germanici solubilis*, seven and a half grains (grm. 0.5) after each meal—or of pancreatin. The popular wines of pepsin are not to be recommended, because of the alcohol they contain.

On the other hand, alkalies have been long employed in chronic gastric catarrh with good effect. Their value is more easily understood to-day, because we know (see the appendix to this chapter) that many disturbances of digestion are associated with an excessive production of acid; still it can not be denied that even in other cases alkaline remedies are sometimes beneficial. This is probably because the alkalies may contribute to the neutralization of abnormally formed acids; because they promote the discharge of the gastric contents; because they tend to clear away the mucus; and because, finally, as has been experimentally shown, bicarbonate of soda, chloride of soda, and carbonic-dioxide gas exercise a stimulating influence upon the secretion of the gastric juice. As is well known, the alkalies are mainly prescribed in the form of alkaline mineral waters. The springs of Carlsbad possess the greatest reputation. Those at Ems, Kissingen, Tarasp, and Vichy also deserve to be mentioned as health resorts for patients with gastric trouble. A good portion of the benefit at these places is, to be sure, dependent upon the fact that many patients are much more apt to follow a strict regimen when they make use of a particular "cure" than when they remain at home.

If the character of the vomitus or of the gastric contents indicates abnormal processes of fermentation in the stomach, the best remedy is probably a methodical lavage of the stomach. We may also try drugs which prevent fermentation, the most important of which is again hydrochloric acid in rather large doses. Other remedies for this purpose are salicylic acid in powders of eight grains (grm. 0.5) each; creasote, two or three half-grain pills (grm. 0.03) a day; and benzine, twenty drops in milk.

The best drugs to stimulate the secretion of gastric juice are the bitters. It is

this property which has earned them the name of stomachic tonics. Compound tincture of gentian, tincture of *nux vomica*, tinctura amara, and tinctura calami, P. G., quassia and columbo—these are the most employed. In general, however, they are not very efficient. An excellent tonic in many of these cases is cundurango bark. A decoction may be made (15 parts to 200 of water); or we may write for powders of seventy-five grains (grm. 5) each, one powder being made into one or two cups of infusion by the patient himself.

A few remedies remain to be mentioned, which are said to exert a direct beneficial influence upon the catarrh, and which many physicians extol highly. Their efficacy, however, is somewhat problematical. We refer chiefly to subnitrate of bismuth, sulphate of zinc, and nitrate of silver.

Certain symptoms may demand especial treatment, such as vomiting. It will usually yield to regular and persistent washing out of the stomach. Other remedies are small bits of ice, and minute doses of opium or chloral. Potassic bromide may also be tried.

Violent gastralgia requires narcotics, such as hydrocyanic acid and morphine. "Sour stomach" may be relieved by a pinch of bicarbonate of soda, or of calcined magnesia. Persistent anorexia may yield to the bitters mentioned above, or to small doses of quinine. If the bad taste in the mouth is annoying, the mouth should be frequently rinsed out with Seltzer water, a one-per-cent. solution of carbolic acid, or five drops of tincture of myrrh to a glass of water. For habitual constipation, enemata, or the various mineral waters, are good; also Carlsbad salts. In obstinate cases pills of rhubarb or aloes may be employed. Still, we ought never to forget that the infrequency of the stools is often merely a natural consequence of the scanty diet, and that it is therefore possible to do harm with our purgatives. Iron is often prescribed for the concomitant anemia; but it should be employed cautiously, for it is often ill borne in gastric disease.

#### APPENDIX.

##### HYPERACIDITY AND HYPERSECRETION OF THE GASTRIC JUICE. ACID DYSPEPSIA.

It was formerly believed that in most cases of disturbed digestion there was a diminished secretion of the gastric juice, and in particular of hydrochloric acid; but the newer investigations of Reichmann, Riegel and others, have taught us that it is by no means rare to find in these cases an exaggeration of the production of acid and an increased secretion of the gastric juice. Hyperacidity is the term applied to that condition in which at the time of digestion an abnormally large amount of hydrochloric acid (0.4 to 0.6 per cent.) is found in the gastric juice. "Hypersecretion" refers to that anomaly where at other times than when digestion is taking place, when the stomach is empty, there is invariably to be found a considerable amount of strongly acid gastric juice in the stomach. Hyperacidity may exist independently of hypersecretion, while hypersecretion is usually conjoined with excessive secretion of acid. Probably, therefore, hypersecretion is merely an exaggeration of those processes which lead to hyperacidity.

Hyperacidity may usually be demonstrated merely by obtaining an unusually strong reaction for hydrochloric acid with methyl-violet in the gastric contents, but a more accurate diagnosis of course requires a quantitative estimation of the acidity. The recognition of hypersecretion is not easy. If we introduce a tube into an empty stomach—the best time being early in the morning—we shall find that the stomach is never empty, but that it invariably contains a larger or smaller amount of strongly acid liquid unmixed with particles of food, and that

this liquid evinces its character as gastric juice by possessing an abundant amount of hydrochloric acid and digestive properties.

As to the causes of hyperacidity and hypersecretion, little as yet is known. They are perhaps occasioned by conditions of nervous irritation, or perhaps by special forms of catarrh. It is certain that gastric ulcer is very frequently associated with hyperacidity (see below).

As we have already mentioned, increased production of acid and of gastric juice is by no means rare, and therefore it is of great practical importance. These conditions occasion quite severe dyspepsia, which is usually termed *dyspepsia acida*. The symptoms of which such patients complain are mainly pain and extremely sour eructations, often associated with pyrosis. The pain is usually described as burning, and it is located mainly in the region of the stomach, but usually radiates toward the navel. It occurs sometimes independently of the ingestion of food (hypersecretion?), sometimes an hour or an hour and a half after eating (hyperacidity?). The extremely sour eructations take place usually at the time of digestion. Vomiting is not very frequent, but it may occur. The appetite is in many cases diminished, but in others it is not much affected. Often there is complaint of great thirst. The general nutrition in many cases remains tolerably fair. In other cases the patients become decidedly emaciated.

Although the above symptoms, and in particular the sour eructations and the burning pains in the stomach, often of themselves arouse a suspicion of acid dyspepsia, yet the absolute diagnosis requires investigation by means of the stomach-tube. The particulars relating to this have been already detailed. It remains only to add that in testing the digestive power we usually find a satisfactory digestion of albumen, but a very incomplete digestion of starchy food. This is probably in main part dependent upon the fact that the excessive acidity of the gastric juice inhibits the amylolytic action of the saliva in the stomach (Ewald and Boas), but it may also partially result from the hindrance to the propulsion of the food from the stomach, because of a spasmodic closure of the pylorus (Riegel).

The treatment of acid dyspepsia consists first in the employment of alkalies, such as bicarbonate of soda, in sufficient doses, say seventy-five grains (grm. 5), several times a day. The use of alkaline waters, such as Carlsbad, is also often attended with good results, particularly as these dilute the gastric juice and thus diminish the irritation caused by the acidity. For this reason many patients find great relief from taking warm tea at the time of the pain. If the discomfort is great, the most efficient remedy is certainly a methodical lavage of the stomach. With regard to the best diet, we may allow flesh in a sufficient amount, while carbohydrates as above mentioned must be enjoyed in moderation.

### CHAPTER III.

#### PHLEGMONOUS GASTRITIS.

(*Purulent Inflammation of the Stomach.*)

PURULENT inflammation of the stomach is very rare, and little is yet known about it. In most cases no special causes for it have been ascertainable. It is occasionally one of the symptoms of grave pyæmic or puerperal inflammation.

Two forms are distinguished—a diffuse and a limited variety. The latter is equivalent to gastric abscess. The submucous layer is almost invariably the chief seat of suppuration. From this starting-point the process invades the muscular and serous coats on the one hand, and the mucous membrane itself on the other.

The usual symptoms are violent gastric derangement, with pain and vomiting, high fever, and the indications of constitutional infection, namely, headache, delirium, and general prostration. Sometimes the disease is quickly fatal, sometimes it runs a more chronic course. The few cases in which recovery has been reported are somewhat obscure.

The disease can never be diagnosticated with absolute certainty. Treatment must be purely symptomatic. Ice, both internally and externally, and the narcotics, are chiefly employed.

#### CHAPTER IV.

##### GASTRIC ULCER.

(Simple or Round Ulcer of the Stomach.)

**Ætiology.**—Since Cruveilhier gave the first accurate description of gastric ulcer, numerous explanations of its occurrence have been propounded. Even yet there is no universally accepted view. There is, however, one point about which most authors are agreed, namely, that the ulcer is due to a self-digestion of the stomach at one limited spot. Hence it is frequently termed "peptic ulcer of the stomach."

Apart from the inherent vital resisting power of the cells, the reason that the stomach is not continually being digested by its own juices is, as we all know, chiefly the alkalinity of the blood, which is constantly coursing through the mucous membrane. Wherever the circulation is in any way interfered with, we should therefore expect to find, and we do find, that the mucous membrane begins to be digested.\* If, as a result of inflammation, a minute hæmorrhage occurs at any point, the little area thus deprived of its blood-supply is at once digested. This is what is called a "hæmorrhagic erosion." The experiment of occluding the arterioles of the gastric mucous membrane with emboli has been tried by Panum and Cohnheim. The resulting hæmorrhagic infarctions were transformed into ulcers. Just what the essential conditions are, in man, under which a local disturbance of the circulation and a consequent round ulcer of the stomach are produced, we are thus far confined to conjecture. Virchow assumed that most cases were the result of thrombosis or embolism of the minute blood-vessels, caused by various diseases. Klebs suggested the possibility of a local spasm in the vessel. Böttcher has succeeded in detecting numerous colonies of micrococci in the margins of gastric ulcers, and regards them as the cause. As we have already said, however, no one of these views has been universally accepted.

It may be that in many cases some local injury of the mucous membrane is the original cause of the ulceration. Such possible causes are burns or mechanical lesions, including blows over the stomach. But even then we are unable to explain why the ulcers should spread laterally and downward. For all gastric ulcers experimentally produced, whether by embolism, contusion, burning, or even cauterization (as practiced by Quinke), exhibit a decided tendency to rapid healing. It has therefore been suggested that the further extension of the ulcers, in such cases, is due to an abnormally great acidity of the gastric juice (*vide infra*).

\* After the circulation is terminated by death, this digestive process at once begins, producing the softening of the stomach, or *gastromalacia*, frequently found at autopsies. There has been much discussion as to the origin of this condition, but it now seems indubitable that it is in every instance a post-mortem change.

Ulcer of the stomach is commonest in young adults, between seventeen and twenty-five years of age. It is rare in children; less so in older people. The disease is noticeably more frequent in females than in males. It is more prone to attack the weakly, anæmic, and chlorotic than the vigorous.

**Pathology.**—The ulcer is usually of a circular shape. Its borders are sharp; the walls often slope inward, giving the ulcer the form of a shallow funnel. Its base is almost always perfectly clean. If superficial, it does not extend farther than to the muscular coat, but it may be deep enough to expose the serous membrane, or even to perforate it (*vide infra*). The size varies greatly. Some are hardly as large as a pea; others may measure ten to fifteen centimetres in their greatest diameter. As to position, most of them are found near the pylorus. They attack the posterior wall of the stomach, particularly the neighborhood of the lesser curvature, more frequently than the anterior wall. As a rule, we find but a single ulcer, although exceptions to this statement are not very rare.

If an ulcer of any size heals, a scar is formed, with radiating lines and often of considerable size. Cicatricial contraction may alter the shape of the stomach considerably. Pyloric ulcers may leave scars which eventually produce stricture of the pylorus and consequent dilatation of the stomach.

If the ulcer attacks the serous membrane, perforation may finally result, unless an adhesive peritonitis attaches the stomach, at the point threatened, to some neighboring organ. The ulcers being usually on the posterior wall of the stomach, it is oftenest the pancreas to which the stomach becomes adherent. In other instances it is the liver, transverse colon, diaphragm, or spleen. If the ulcer penetrates organs to which the stomach has become attached in this way, the inflammation extends, so as to cause empyema, for example, or hepatic abscess; or the pleura, lungs, pericardium, or transverse colon may be perforated. We shall revert to this subject under the symptomatology of gastric ulcer.

The ulcer may cause erosion of a blood-vessel, and thus give rise to one of the most important symptoms of the disease, namely, gastric hæmorrhage.

**Clinical History.**—There may be absolutely no symptoms. It is not a rare thing to find at autopsies a still active ulcer of the stomach, or the cicatrix left by one, in subjects who never had during life any gastric disturbances whatever. Nor is it exceptional for a person suddenly to exhibit grave symptoms, like gastric hæmorrhage, or peritonitis due to perforation, where there has been no reason previously to apprehend the existence of an ulcer.

In other instances the ulcer does, indeed, give rise to symptoms, but they are not sufficiently characteristic to point to the correct diagnosis. There are anorexia, occasional gastralgia, vomiting, and eructations—symptoms which might with equal probability be referred to a simple chronic catarrh. In fact, it seems likely that the ulcer has little share in their production, and that they are mainly due to a co-existing catarrh. In these cases, also, grave symptoms consequent upon the ulceration may suddenly arise.

In a third class of cases there are symptoms which are to a certain extent characteristic, and lead with more or less definiteness to the true diagnosis. These "symptoms of ulcer" are chiefly a peculiar epigastric pain, which is usually intermittent, and vomiting, or, what is yet more distinctive, the vomiting of blood, or hæmatemesis. These symptoms and their diagnostic value we must now consider in detail.

Pain in the stomach is one of the most frequent symptoms of round ulcer. Its forms are very diverse. Often the patient complains only of a diffuse, painful sensation of pressure referred to the entire region of the stomach. This may be uninterrupted, or it may occur only after meals, or after excessive exertion, or as the result of some other special cause. This sort of pain is the least diagnostic of

any, inasmuch as exactly similar sensations may be caused by a simple chronic catarrh. More characteristic of ulcer is a decided cardialgia—that is, a very violent pain, coming on at intervals like neuralgia. It is described as “cutting,” “tearing,” “boring,” and the like. The pain may come on irregularly at any hour; or it may occur with considerable regularity at the end of a definite time after eating, say half an hour or an hour. It is felt chiefly in the epigastrium, but not infrequently extends toward the umbilicus, backward toward the vertebrae, into the thorax, or even into the upper extremities. In many instances a marked sensation of thoracic oppression accompanies it. Another characteristic point is that a change of position may sometimes affect the severity of the pain. It is sometimes observed that the patient, when lying upon his right side, feels violent pain, which is at once relieved by changing to the left side, probably because the ulcer is located near the pylorus. An attack of cardialgia may last for a few minutes or for several hours. It is commonly thought to be due to the direct irritation of the ends of nerves lying exposed at the base of the ulcer. As an isolated symptom, this cardialgia can not be distinguished from the purely nervous variety, but, taken in connection with other symptoms, it is often a great aid to diagnosis. We should add that precisely similar attacks of cardialgia may be produced by the scars of ulcers which have already entirely healed.

A third variety of pain may be observed in gastric ulcer. The suffering may be localized in a very limited area. Such pain is thought to be due to irritation of the floor of the ulcer by food, or to its edges being pulled upon during the movements of the organ. It generally comes on after eating, and ceases if the stomach is perfectly quiet. In position, this pain is generally epigastric, but sometimes it is umbilical, or even, now and then, more toward the back. In many cases of gastric ulcer there is also tenderness on pressure in a quite sharply defined area and at one particular spot. Most authors regard the accurately localized pain as the most nearly pathognomonic; but it must be said that it is decidedly the least frequently exhibited of any. Transitional forms and combinations of the various kinds of pain are often observed.

Vomiting is a very frequent symptom of gastric ulcer, but if the vomitus is composed of nothing except food, or food mixed with mucus or bile, the symptom is not at all characteristic. In quite a large proportion of cases, however (about one third), hæmatemesis occurs either once or repeatedly. The vomiting of a considerable amount of blood is beyond doubt the most important factor in diagnosing gastric ulcer. Often the sudden occurrence of a decided hæmatemesis enables one to diagnose a gastric ulcer with an approach to certainty. If there is no vomiting of blood whatever, there is much more doubt about the existence of an ulcer.

Hæmatemesis is frequently the symptom which first leads the patient to apply to a physician. Up to this time he may have felt perfectly well, or, although there may have been some gastric derangement, he has not thought anything of it. The patient suddenly becomes faint, perhaps while he is pursuing his regular occupation, or it may be at night. He feels dizzy, and it looks black before his eyes. Then he has nausea, and finally is obliged to vomit. The vomitus is either pure blood, or a mixture of blood and food. It is partly coagulated, and often has a rather dark or blackish color. This change in color, as well as the coagulation, is due to the action of the gastric juice. The amount varies greatly in different cases: there may be a quart or more. Not infrequently blood is repeatedly vomited either at short intervals or on successive days. Part of the blood escapes through the pylorus, so that, after a profuse gastric hæmorrhage, blood is sure to be found in the stools. In them it is black and tarry. Exceptionally it happens that all the blood, beyond what is absorbed from the intestinal canal, passes off

*per anum*, so that none whatever is vomited. In such cases it is often a difficult matter to locate the hæmorrhage.

The consequences of gastric hæmorrhage depend, of course, chiefly on the amount of blood lost. Sometimes, although fortunately rarely, a large blood-vessel is eroded and the patient dies. This event may be sudden, or it may occur more gradually under the influence of repeated hæmorrhages and after a few days, during which all the symptoms of acute anæmia are exhibited. On the other hand, the loss of blood may be so insignificant as to produce no especial symptoms. In most instances life is not actually threatened, but yet the signs and results of a more or less marked general anæmia are clearly visible.

In such cases the patient feels extremely exhausted, and at once takes to his bed. He has also all the subjective symptoms of cerebral anæmia. There are vertigo, tinnitus aurium, specks before the eyes, frequent gaping, and sometimes headache. To assume an erect posture aggravates the disturbance. There is usually excessive thirst. Now and then a temporary amaurosis has followed an excessive hæmorrhage.

Objectively, we notice at once the excessive pallor of the skin, particularly of the face. The lips and conjunctivæ are also blanched. The pulse is rapid, and often ill sustained. For some days there may be anæmic murmurs over the heart, and there is a distinct sound to be heard in the femoral arteries. A moderate rise of temperature is very common. This is known as the anæmic fever. The urine is pale, and usually rather abundant. Its specific gravity is not infrequently relatively high, namely, 1015 to 1020. All these symptoms are directly referable to the loss of blood, and will be discussed with greater detail in the section on anæmia.

If the hæmorrhage is not repeated, the patient gradually regains his strength. To be sure, the pallor usually persists for a long while, but the disagreeable symptoms gradually abate. Where gastric discomfort has existed previously to the hæmorrhage, it often disappears entirely after it—a circumstance which is probably in part due to the excessive caution of the patient thereafter. At the end of a few weeks the patient often feels perfectly well again; and, indeed, recovery is not infrequently complete and permanent. In other cases, however, the symptoms of ulcer return, sooner or later.

Other symptoms than those already discussed are more uncertain. Anorexia, eructations, and obstinate constipation may be present, or may be wholly wanting. In cases of suspected ulcer, it is usually inadvisable to introduce the stomach-tube for diagnostic purposes, because bleeding or perforation might result. Investigations have shown that frequently there is no serious derangement of digestion. It is interesting, however, that very often the gastric juice is excessively acid (hyperacidity, Riegel). If there be imperfect digestion, it is probably due not so much to the ulcer as to a coincident gastric catarrh. The general nutrition often suffers comparatively little, unless there are persistent anorexia and vomiting.

An event which has been already mentioned under pathology—namely, perforation of the ulcer—is of great clinical importance. It would be impossible to particularize here all the possibilities incident to it. We shall confine ourselves to the two most important because most frequent varieties of perforation: (1) into the peritoneal cavity, causing peritonitis, and (2) into the left pleura, or left lung.

Perforation into the peritoneal cavity leads almost invariably to a quickly fatal peritonitis. When the ulcer has previously caused few symptoms, if any, the excruciating abdominal pain, tympanites, vomiting, collapse, and sudden death of peritonitis may abruptly supervene upon a state of apparently perfect health. It is the exception to have the peritonitis limited. This is more apt to occur if adhesions have been formed previously. An encapsulated abscess then results, which

points either into the intestine or externally, and may rarely terminate in complete recovery.

Perforation into the left pleural cavity we have observed repeatedly. It causes a purulent or septic pleurisy on that side, and pulmonary gangrene may develop at the same time or later, as a result of perforation into the lung. Whenever we meet a case of apparently spontaneous, left-sided empyema, we should at any rate always think of the possibility of gastric ulcer.

The general course of round ulcer of the stomach varies, as we can see, so greatly in different cases that it can not be depicted simply. Complete recovery is by no means rare. In other cases the symptoms persist for years with varying intensity. We have already spoken of the hæmorrhage and perforation which may suddenly intervene, and of their significance. Relapses are not infrequent, even after apparent recovery. If the ulcer cicatrizes, the scar itself may give rise to persistent disturbances; there may be obstinate cardialgia, or, if the scar is at the pylorus, dilatation of the stomach (*vide infra*) may gradually be developed.

**Diagnosis.**—The diagnosis can be made only when the above-mentioned characteristic symptoms are present. Of these, hæmatemesis is by far the most significant, for it is with very few exceptions the result of gastric ulcer. Particularly is this true of individuals under middle age.—But how shall we determine whether the blood ejected did not come from the nose or the lungs, rather than the stomach? The answer is not always easy. If an epistaxis occurs at night, a part of the blood often flows back into the naso-pharynx, and, being swallowed, excites vomiting, so that a gastric hæmorrhage is suggested. It is also very important for the physician to remember that blood may be "vomited" in hysterical cases. If there is also nervous cardialgia, one might easily be misled to assume the existence of a gastric ulcer. Other hysterical symptoms (see the chapter on hysteria) and the character of the blood will usually guide us to a correct diagnosis. The blood probably comes in most cases not from the stomach, but from the gums or pharynx, and it is consequently of a comparatively bright color and rather watery.

The diagnosis between gastric and pulmonary hæmorrhage in doubtful cases depends on the following factors: 1. The previous condition of the patient—whether he has had cough, expectoration, and other pulmonary symptoms, or, on the other hand, gastric pain and vomiting. 2. On the character of the hæmorrhage, whether accompanied by vomiting or by cough. But there may have been both. Violent vomiting may excite a cough; and, on the other hand, blood which has been coughed up, may be in part swallowed and induce vomiting. 3. On the character of the blood: if from the lungs, it is usually bright-red and frothy, containing bubbles of air, with few clots, and of alkaline reaction. In gastric hæmorrhage it is usually dark, mixed with food, partly clotted, and acid in reaction. 4. On the results of physical examination. In this, of course, we must be extremely cautious after a hæmorrhage, lest the movements of the patient excite fresh bleeding; and yet we may be able, from the general condition of the patient, or from dullness at the apices, or moist râles, to demonstrate pulmonary disease. If the blood came from the stomach, we usually detect nothing but the signs of anæmia. 5. The subsequent symptoms. In cases of pulmonary hæmorrhage there is almost sure to be an expectoration, for the next few days, either of pure blood or of matter stained with blood; and, in gastric hæmorrhage, the next dejection will almost certainly be black, from the presence of decomposed blood. In doubtful cases, the appearance of blood in the stools almost invariably settles the question in favor of gastric hæmorrhage.

In cases of gastric ulcer, unaccompanied by hæmatemesis, the diagnosis is only more or less probable, not certain. The existence of cardialgia and localized pain

in the stomach must always make us consider the possibility of an ulcer, but we can not be positive about it.

The differential diagnosis between gastric ulcer and purely nervous cardialgia, and between ulcer and cancer, will be discussed later in the appropriate chapters.

**Prognosis.**—The dangers in ulcer of the stomach, particularly hæmorrhage and perforation, have already been spoken of. Whether these misfortunes will actually occur in any individual case, and when, we can not determine.

There can be no doubt that a large number of ulcers heal perfectly; but, as we have already said, even the resulting scar may cause trouble. This possibility must be borne in mind. Of these persistent symptoms cardialgia is the most frequent. Dilatation is also possible. And, finally, it is probably not a very rare event that cancer eventually develops in the floor of the old ulcer. We shall revert to this matter under cancer of the stomach.

**Treatment.**—If the diagnosis of gastric ulcer is evident, or if the symptoms are of such a nature that there is a justifiable suspicion of an ulcer, the patient should be urgently advised to submit himself to careful and methodical treatment; for it is only by means of a sufficiently persistent and properly conducted treatment that we can hope for good therapeutic results in ulcer of the stomach.

The essential condition is, that the patient should keep his bed for the first part of the treatment, at least for two or three weeks. Complete bodily rest is certainly an important assistance in promoting healing of the ulcer. The patient should also have moist compresses, or, still better, as Leube has advised, warm poultices applied all day long to the epigastrium. These poultices give great relief to the pain. In the third place—and this is probably the important matter—the patient must keep strictly to an accurately prescribed diet. Every mechanical and chemical irritation of the floor of the ulcer must be avoided, and therefore, at first, liquid nourishment alone is to be permitted. It is best to allow the patient, for the first ten days, milk, bouillon, and at the most some eggs and thoroughly moistened bread. A very suitable article of diet is soup made out of the Leube-Rosenthal solution of meat. In the fourth and last place, we should consider the hyperacidity of the gastric juice, which, as has been already said, exists in the case of ulcer. The patient therefore should be given every day a tablespoonful of Carlsbad salts, dissolved in a pint of warm water, to be taken in three or four divided doses during the forenoon and afternoon. If treatment of this sort is strictly carried out, the discomforts of the patient, his pain and vomiting, will abate in a few days. After some ten days have passed, if the patient feels well, he may cautiously begin to eat such food as the brain of calves boiled, boiled pigeon, boiled fowl, and flour gruel. If this dietary makes the pain return, we must fall back upon the first kinds of nourishment. Usually, however, the above-named foods are well borne, so that after another period of eight or ten days the patient may be allowed some beef, such as sirloin or beefsteak, shaved raw ham, and, later, also underdone roast meat, game, veal, fish, and the like. The more severe the earlier symptoms were, the slower and more cautiously will one proceed with changes in diet. If desired, one may also employ either artificial nutriments, such as the meat peptones of Koch and of Kemmerich, and leguminose, and also various kinds of infant foods.

The above methods will usually accomplish all that we can hope to do, and it is not till they prove unavailing that, while persisting in our dietetic treatment, we should try the other remedies, whose efficiency is often extolled but has never been demonstrated. Among these, the favorite is subnitrate of bismuth in powders of five to fifteen grains (grm. 0.30-1.00) each, mixed with sugar. To this we may add a sixth of a grain (grm. 0.01) of morphine, if there is cardialgia. One powder is to be given three times a day, fifteen minutes before meals. Nitrate of silver is

also frequently administered in pills of one sixth of a grain (grm. 0.01) thrice daily; or in a solution of 1 to 400, of which the dose is one or two teaspoonfuls.

Finally, there are special symptoms which may need to be relieved. Violent pain, when not yielding to regulation of the diet, demands morphine. We may also try warm or cold applications, or chloroform, externally. Gerhardt recommends three or four drops of liquor ferri chloridi in a wineglass of water, for the relief of pain.

Excessive vomiting and persistent nausea are likewise to be combated by the narcotics. Opium is the best; morphine, chloral, and bromide of potash may also be tried. If there be no improvement, we may try creasote, or three or four drops of tincture of iodine. At the first appearance of blood in the vomitus the greatest bodily quiet and most careful dieting is absolutely indispensable. For the first day or two it is best to allow nothing except ice-cold milk and bits of ice in the mouth to appease the burning thirst. The patient must lie as quietly as possible in bed. A flat ice-bag, not too heavy, should be placed on the epigastrium. In case of persistent nausea or eructations, small doses of morphine are to be prescribed. We must wait till four or five days after the hæmorrhage before we cautiously increase the amount of nourishment, which must still be liquid.

If peritonitis appears as the result of perforation, the best means to try are the outward application of ice to the epigastrium and the internal use of opium in large amounts—that is, half a grain to a grain (grm. 0.03–0.05) every one or two hours. Unfortunately, however, the cases are exceptional in which the peritonitis does not become general. Then, possibly, operative interference might be of some avail. Other measures are almost hopeless. We may try to alleviate the pain by narcotics, but it is very rarely that we can prevent a fatal issue.

[In cases of recent hæmorrhage or markedly painful digestion, the editor has pursued the following plan of treatment with apparently good results: The most powerful agent in the promotion of cicatrization is rest. Absolute rest in bed is therefore enjoined, with the secondary end in view of reducing the demands of the system. The patient is then fed exclusively by the rectum for at least one week, generally for two weeks, nothing but a little water being given by the mouth. A simple cleansing enema is given once daily; and at six-hour intervals a nutrient enema, six to eight ounces in bulk, and composed of one or two raw eggs, an ounce of expressed beef juice, and fully peptonized milk, is administered. Tolerance by the rectum is promoted by the addition to the enema of a few drops of laudanum. After one or two weeks small quantities of milk at frequent intervals are given by the mouth, and the rectal alimentation is gradually diminished as that of the stomach is increased. Pain usually ceases immediately on the cessation of gastric ingestion, and the loss of weight during a fortnight of rectal feeding is surprisingly small.]

## APPENDIX.

### MELÆNA NEONATORUM.

We desire here also to mention the condition known as *melæna neonatorum*. In rare instances during the first week after birth, hæmorrhages occur from the stomach (*hæmatemesis*), which are sometimes associated with dark, bloody stools. As a rule the hæmorrhages are repeated, so that after a few days death occurs with all the phenomena of anæmia: but, even after what seem to be the worst symptoms, recovery may exceptionally take place.

The cause of *melæna neonatorum* is by no means clear, but in some of the cases small ulcers are found in the mucous membrane of the stomach and

intestine, as to the origin of which we have no certain information. Passive congestion, embolism, and infection have been suggested as causes.

The treatment consists in the application of ice poultices to the abdomen. Liquor ferri perchloridi has been also recommended, in doses of one drop every two hours in oatmeal-water.

## CHAPTER V.

### CANCER OF THE STOMACH.

**Ætiology.**—We can not here discuss the ætiology of carcinoma in general, and we shall therefore merely enumerate the factors which experience has shown to favor the development of cancer in the stomach.

Age has a remarkable influence. Gastric cancer is decidedly most frequent late in life, between the fortieth and sixtieth year. Still it is occasionally seen in younger persons. We have ourselves seen several cases in persons between twenty-two and twenty-five years of age.

Sex is of no importance.

Heredity has a slight but undeniable influence. The most famous example of the transmission of cancer is presented by the family of Napoleon.

The relation of gastric cancer to other antecedent diseases of the stomach is very interesting. Whether frequent errors in diet or the use of alcohol increase the liability to this disease is uncertain. On various sides attention has been called to a possible, and as it seems to us very probable, connection of gastric cancer with antecedent ulcer. Not only at the bedside, but at the post-mortem table, a relatively large number of cases have been observed where cancer had developed on the floor of an old (and usually cicatrized) ulcer. Hauser made the interesting discovery of a-typical growths of epithelium in the scars of gastric ulcers—a phenomenon which points strongly toward the relation suggested.

**Pathology.**—The stomach is a favorite seat for cancer. About a third of all cases of cancer are gastric. The parts of the organ most often attacked are the pyloric end and the lesser curvature. Less frequently the cardiac end and the fundus suffer.

The new growth takes the form either of a circumscribed tumor or of a diffuse infiltration, thickening the walls. The disease invariably originates in the mucous layer, extending thence into the submucous and muscular coats. The connective and muscular tissues in the neighborhood of the cancer are quite often considerably hypertrophied.

Histologically, gastric cancer is of the cylindrical-cell variety, starting from the glandular epithelium. The soft tumors are termed medullary; the firm and hard, scirrhus or fibroid. The medullary cancers are particularly apt to be quite extensively broken down on their exposed surface, thus forming what are known as cancerous ulcers. This seems to be mainly the result of the gastric juice acting on the superficial and insufficiently vascularized portion of the tumor. The base of these ulcers is usually clean, as we should expect from the mode of their production. In many cases of rather young subjects, and also in others, we find colloid cancer. This form also may appear either in nodules or as a diffuse growth, infiltrating the tissues. As to metastasis of gastric cancer, *vide infra*.

**Clinical History.**—Most cases of gastric cancer exhibit a combination of grave digestive disturbances with a relatively rapid loss of flesh and strength. Now and then the gastric symptoms assume less prominence. The chief sign of disease is a constantly progressive marasmus or anæmia, the true cause of which

is either entirely latent or not unmistakably recognizable till late in the illness.

Some of the gastric symptoms are not very characteristic. They merely show that digestion is disordered. There is loss of appetite and distress after meals. The patient complains of a disagreeable sensation of pressure in the epigastrium, increased by food. Sometimes this amounts to actual cardialgia. Many patients are annoyed by frequent eructations. Occasionally vomiting is troublesome; in other instances there is scarcely any. The vomitus may contain nothing but mucus and the ingesta; or it may assume, from the admixture of blood, a very characteristic and somewhat pathognomonic appearance.

Free gastric hæmorrhage and consequent hæmatemesis is exceptional, or at least much less frequent than in ulcer of the stomach; but the vomitus often contains decomposed blood, and in many cases this will be for a time almost a constant appearance. Most of the ulcerated cancers bleed frequently, a little at a time. The escaping blood is broken up by the action of the gastric juice, its red hæmoglobine being transformed into the black hæmatine, which produces that "coffee-ground" or "chocolate-colored" appearance of the vomitus so significant

FIG. 35.—Hæmine crystals.

of the disease. In such cases the presence of blood can be demonstrated conclusively by the spectroscope, or by means of the so-called hæmine reaction. To perform this, a small portion of the vomitus is heated to boiling in a watch-glass, having first been mixed with a little glacial acetic acid and a few crystals of common salt. A drop of this is then allowed to dry upon an object-glass, when the rhombic crystals of hæmine are quickly formed. These crystals have a dark-brown color, and are easily recognized (*vide* Fig. 35). We should mention that in the case of ulcerating carcinoma ven-

tricoli the vomitus may have so foul an odor that it may even be regarded as stercoraceous.

Immediate microscopic examination of the vomitus may reveal red blood-globules. Other characteristic constituents are rare. It is only exceptionally that bits of cancer can be demonstrated. Of course, if seen, they end all doubt. *Sarcinae* are often found, just as in other gastric diseases.

Of great diagnostic importance is the investigation of the gastric juice (*vide supra*, page 378). As Von den Velden first pointed out, in most cases of gastric cancer there is no free hydrochloric acid in the gastric juice, or at least none to be detected by means of the well-known reaction with methyl-violet and the other reagents; while on the other hand lactic acid is not infrequently abundant, and may even be present for a long while after food has been ingested. The digestive power of the gastric juice in persons afflicted with carcinoma is consequently, as may be easily demonstrated by experiment, decidedly below normal. The reason of this frequent absence of free hydrochloric acid in carcinoma is not yet clear. Probably this phenomenon does not depend directly upon the carcinoma, but upon the catarrh of the rest of the gastric mucous membrane which is usually present in cases of carcinoma; and again, when the gastric mucous membrane is much atrophied, as has likewise been repeatedly shown to be the case, the production of hydrochloric acid ceases.

Physical examination of the stomach, and palpation in particular, are of the greatest value. In a large number of cases the new growth can be more or less plainly felt through the abdominal walls, as a hard, nodular tumor. The tumor is situated in the epigastrium, in a majority of cases, but it may be lower down or more to one side, according to the region attacked. It should be remembered

always that a permanent tumor may essentially alter the position of the stomach to which it is attached. As an illustration, a case of pyloric cancer, which we saw, with secondary dilatation of the stomach, had resulted in such a displacement of the pylorus that the tumor was to be felt through the abdominal walls, about a hand's breadth above the symphysis pubis. Sometimes the tumor varies in position according to the fullness of the stomach. The effect of the respiratory movements upon the tumor varies. In some cases, particularly if the tumor is adherent to the liver, it can be plainly felt to move downward with each inspiration, while in other cases it remains perfectly stationary.

In a minority of the cases no tumor can be felt at any time. Under such circumstances the diagnosis can not often be definitely established. The tumor is undiscoverable, first, in most cases of diffuse cancerous infiltration of the stomach-walls. We may, indeed, notice an increased sense of resistance and hardness in the epigastrium, but can not refer this condition with certainty to a new growth. Secondly, the new growth may extend chiefly inward, toward the cavity of the organ, and may thus escape detection. And, finally, the tumor may be so concealed by the liver or the edge of the ribs that it is inaccessible to the touch. Such cancers as attack the cardiac extremity, the posterior wall, or the lesser curvature of the stomach, are particularly apt to be out of reach of palpation.

Percussion of the cancer rarely gives flatness, but instead a muffled tympanitic resonance. This is sometimes an influential factor in the differential diagnosis from cancer of the liver.

The physical examination sometimes yields secondary evidences of cancer, in addition to those which are due directly to the new growth. In most cases of pyloric cancer a resultant dilatation of the stomach can be demonstrated.

Next in importance to the gastric symptoms is the disturbance of general nutrition. Loss of flesh is not rarely the very first symptom which calls the patient's attention to his disease. This wasting is observed earliest in cases which are attended with anorexia and vomiting. The patient also gradually takes on that familiar cachectic look which is characteristic of most cases of cancer. Some patients become excessively anæmic. The skin acquires a waxy pallor, and there are all the symptoms which result from great anæmia, such as cerebral symptoms and functional cardiac murmurs. Sometimes the blood itself presents decided peculiarities in such cases. Thus we may find microcytes and poikilocytes in it. Gastric cancer and pernicious anæmia (*q. v.*) have been repeatedly confounded. The cause of this excessive anæmia is not always perfectly clear. In one such case we made the interesting discovery of extremely abundant metastatic cancer in the bones. As the bone marrow is known to have something to do with the production of the blood, it may be that the anæmia was due to this abnormal condition. At any rate, the grave anæmia which results from cancer, and sometimes also from other chronic diseases of the stomach, particularly gastric ulcer, can not be regarded in just the same light as are the loss of flesh and the cachexia. Often the anæmia is very great before the general nutrition has suffered much impairment.

When the disease is pretty well advanced there may be moderate cedema of the ankles and the back of the hands. This is to be explained, as in other cachectic and anæmic conditions, by the impaired nutrition of the vascular walls, the hydræmia, and the cardiac weakness.

Special derangements of other organs are relatively infrequent. Metastatic cancer is of importance. It attacks the liver chiefly. If the hepatic new growth is considerable it may quite overshadow the primary cancer. Secondary carcinoma of the peritonæum is also apt to cause marked symptoms, such as ascites and abdominal pain. Secondary cancer may also involve the mesenteric and retro-

peritoneal lymph-glands, the lungs, and other organs, but does not usually give rise to striking symptoms when so situated. It may be added that patients with cancer of the stomach sometimes present a swelling of the lymphatic glands above the clavicle, especially on the left side, and that many authors regard this fact as of some value in making a diagnosis.

Direct extension of the new growth into neighboring organs is not very frequent. We will venture to mention one case which we saw, on account of its great rarity. The new growth caused adhesion of the anterior wall of the stomach to the abdominal walls, and then, penetrating through them and the skin of the epigastrium, finally appeared as a tumor, of about the size of one's fist, projecting outward. If a cancer ulcerates, it may destroy all the layers of the stomach, and result in perforation and secondary peritonitis; or, if previous adhesions have been formed, the perforation may open up an abnormal communication between the stomach and some neighboring part of the intestine. The transverse colon is the part usually perforated; less often the small intestine.

As to the bowels, constipation is the rule. Diarrhœa is rare. The urine is usually pale and but slightly acid. Its amount is diminished, as we should expect from the slight amount of nourishment taken, and from the vomiting. Over the heart we may sometimes hear soft anæmic murmurs. The pulse is usually accelerated, although, if there be extreme marasmus, it may be slow. The temperature is normal, or even subnormal. If there is some inflammatory complication, or if the anæmia is extreme, fever may occur.

The entire duration of the disease may occupy one or two years. It is exceptional for it to last longer, except where the cancer develops in the floor of a pre-existing ulcer. In this event, the symptoms of ulcer gradually give place to those of cancer. In individual cases the disease, of course, exhibits many variations and departures from the typical course. Sometimes the constitutional symptoms of weakness and emaciation are more prominent, and sometimes the distinctively gastric disorders.

The fatal termination is usually preceded by the symptoms of constantly increasing weakness. It may be hastened by complications. Now and then grave nervous symptoms appear, often quite suddenly. The patient falls into a condition resembling that of diabetic coma (*q. v.*), he is somnolent, and has a peculiar dyspnoea, with deep and labored respirations, and such an attack almost always ends fatally. Recovery from cancer of the stomach is unknown.

**Diagnosis.**—In addition to the ordinary symptoms common to most gastric disorders, such as pain, eructations, and vomiting, the distinctive factor in diagnosis is the discovery of a tumor connected with the stomach. The demonstration of this is almost conclusive. Other subsidiary evidence can be obtained in most instances. The patient is wasted, has a cachectic look, and is somewhat advanced in years. The most characteristic gastric symptom, as we have already said, is coffee-ground vomitus, containing blood.

It is not always easy, nor even possible, to make sure that a tumor in this region is really of gastric origin. The chief characteristics of the tumor of gastric cancer have already been mentioned. The main thing to exclude is cancer of the left lobe of the liver, or of the pancreas, omentum, or transverse colon. No general scheme for the differential diagnosis between these and the gastric disease can be given, for the circumstances and difficulties vary with almost every case. A careful consideration of all the facts, and wide personal experience at the bedside and the post-mortem table, are requisite here; and yet the most practiced diagnostician may be misled.

We may be able, however, to feel a tumor plainly, and to be sure that it is gastric, and still find it difficult, or even impossible, to determine whether it is

cancerous, or whether it is not a circumscribed induration and thickening resulting from an ulcer of the stomach. This is particularly true of small tumors near the pylorus, attended with secondary dilatation. The clinical symptoms are usually valueless here, for stenosis of the pylorus must produce identically the same symptoms in either case. The age of the patient, the duration of the disease, and possibly the history of characteristic symptoms earlier in the illness, may enable us to reach a probable diagnosis. In this connection it is also to be considered that, as already mentioned, the scars of old ulcers not infrequently form the basis for the development of a cancer. The previous history of the case may present such symptoms as cardialgia and hæmatemesis, indicating that an ulcer has existed, while the objective examination, by demonstrating a tumor and the absence of free hydrochloric acid, leads us to diagnosticate the later formation of a carcinoma. In such cases, and indeed in any doubtful ones, we may test the contents of the stomach for free hydrochloric acid, and, if this is invariably absent, cancer may be inferred.

Here we should add that, even without any evidence of previous ulceration, there may be a simple non-cancerous hypertrophy of the pylorus with consequent stenosis. This occurrence we can affirm from our own experience. The tumor can not be distinguished clinically from the carcinoma of the pylorus, and not infrequently the autopsy itself will not enable us to determine at once whether there is a carcinoma or a simple ulcerative scar or hypertrophy. Absolute certainty is to be gained in such cases by a microscopic examination of the tumor, and by the discovery of metastatic growths, if there be any.

In cases of gastric carcinoma where there is no tumor to be felt, it is always very difficult to make an absolute diagnosis. In general, we should consider the possibility of a cancer in every case where a patient of advanced years complains of severe gastric symptoms without any other demonstrable cause. The more evident the constitutional symptoms of cancer, such as increasing emaciation and cachexia, the more reason is there for fearing the existence of a malignant growth. Here the investigation of the gastric contents is very important. If there is good evidence of hydrochloric acid in the gastric juice (*vide supra*), this is certainly an important argument against the assumption of a cancer. On the other hand, if there is no hydrochloric-acid reaction the suspicion of cancer will be decidedly strengthened, although by no means assured, since severe atrophic catarrh of the stomach may be associated with the complete absence of hydrochloric acid. If one finds decomposed blood in the gastric contents (coffee-ground vomiting, *vide supra*), this, as has been stated, is an almost sure sign of carcinoma.

To distinguish between ulcer and cancer of the stomach may sometimes be a difficult matter. In general, however, we shall be enabled to form a diagnosis by considering the much longer course of the disease in ulcer, as well as the usual youthfulness of the patient, the abundant presence of hydrochloric acid in the gastric juice, the characteristic vomitus, and the hæmatemesis.

**Treatment.**—As to treatment, we must be content if we relieve the patient's suffering. We possess no means of antagonizing the new growth. The bark of cundurango, which Friedreich recommended a few years ago, has not proved efficient. It may, however, be given with some advantage, as it seems to be a good stomachic tonic. A decoction may be made of 15 parts of the bark to 150 of water, and 10 parts of syrup of orange-peel may be added to improve the taste.

The only possibility of a cure of gastric cancer lies in the operative removal of the same, as first carried out by Billroth. Numerous attempts at operation in the last few years have many of them resulted unfortunately, but a few most favorably. We are therefore thoroughly justified, in all cases where we see any possibility of operative interference, to propose an exploratory incision. After the

tumor is laid bare, we may then determine whether the case is operable or not. We can not here enter into particulars upon the subject.

The symptomatic treatment of gastric carcinoma does not differ greatly from that repeatedly described in the preceding chapters. The diet must be regulated, and the administration of hydrochloric acid is important, inasmuch as we know it to be absent from the gastric juice in this disease; otherwise we merely fulfill such indications as arise. For pain, we use the narcotics, and warm or cold applications. If there is persistent vomiting, we give small doses of opium or morphine, chloral, bits of ice, creasote, or tincture of iodine. For acid eructations, we prescribe bicarbonate of soda or magnesia. Very considerable, although unfortunately only temporary, benefit is derived from washing out the stomach. The most suitable cases for this are those of pyloric cancer with consequent dilatation. The various stomachic tonics and bitters must not be forgotten. Our chief aim must be to maintain the patient's strength as long as possible, and to do what we can, morally as well as physically, to alleviate his unhappy fate.

## CHAPTER VI.

### DILATATION OF THE STOMACH.

**Ætiology and Pathology.**—Dilatation of the stomach is, in a majority of instances, a secondary condition, the result of pyloric constriction. As we have already seen in the preceding chapters, this constriction is usually due either to cancer or some other new growth, or to the scars of ulcers. Narrowing produced by pressure from without is relatively infrequent. Tumors in the neighborhood may, however, thus cause dilatation; and, if Bartels be correct, a movable right kidney (*q. v.*) may also compress the pylorus or the beginning of the duodenum sufficiently to produce the same result.

The manner in which the stenosis leads to dilatation is perfectly analogous with that in which stenosis of the aorta causes dilatation of the left ventricle. The propulsion of food out of the stomach into the duodenum becomes more difficult, and consequently the muscular fibers of the stomach are aroused to abnormal activity, that this hindrance may be at least in part if not wholly overcome. As a physiological sequence, we find in most cases of pyloric stenosis the muscular coat hypertrophied, and particularly so in the neighborhood of the pylorus. It is not till the muscle proves inadequate to overcome the obstruction that the dilatation begins. A portion of the ingesta remains in the stomach, and the bulk of this stagnating mass gradually increases. Its weight and pressure have a direct mechanical influence in promoting the gradual expansion of the organ. In addition, the processes of decomposition usually attack the contents of the stomach, and the gases thus generated contribute largely to the mechanical dilatation. Speedily these abnormal chemical and other irritants excite catarrh. The catarrh lessens the resisting powers of the tissues, interferes with the absorption of the contents of the stomach, and in both ways tends to increase the dilatation. The united effect of all these pernicious influences may finally be to produce a dilatation up to three or four times the normal volume of the organ, the flabby fundus hanging down like a great bag into the hypogastrium.

In a smaller number of cases of dilatation we find no stenosis of the pylorus. A large dilatation of this sort is very rare. Smaller degrees of enlargement may frequently exist, but still they are so difficult to diagnosticate with certainty that we can not really say just how frequent they are. The cause of such dilatations

is in many instances an impaired power of resistance, affecting chiefly the muscular layer. This condition may sometimes be due to congenital weakness of the muscular fibers, which not only makes them more yielding, but also favors the retention and stagnation of food in the stomach. In other cases the walls are weakened by disease. Thus a persistent chronic catarrh may lead to moderate dilatation; or constitutional weakness resulting from anemia or severe illness sometimes renders the gastric muscular fibers so weak as to permit dilatation. In all such cases muscular insufficiency is the chief factor, because it favors the accumulation of ingesta within the stomach. In chronic gastric catarrh, it is probable that the muscular fibers become not merely weak but paretic, just as the muscles of the larynx frequently do in laryngeal catarrh.

One factor of gastric dilatation remains to be mentioned. It is the habitual overloading of the stomach with ingesta. That gluttons and drunkards are liable to dilatation of the stomach has long been a familiar fact. It also occurs among the indigent, who are obliged to make up for the poor quality of their nutriment (e. g., potatoes) by taking very large amounts of it. Such a condition may well be compared to cardiac dilatation from excessive arterial tension, and may be termed "overstraining of the stomach." The condition does not become strictly pathological till compensation begins to be insufficient, so that even the hypertrophied muscles are no longer equal to the task of propelling the food properly into the duodenum. In diabetes, excessive ingestion and deficient nutrition combine to produce dilatation, and it has been repeatedly observed in this disease.

**Symptoms and Diagnosis.**—The gastric symptoms are only in part due to the dilatation, being also due to the original lesion or to other attendant circumstances. Most patients complain of loss of appetite, frequent or constant pressure in the region of the stomach, heartburn, eructations,\* and vomiting. The vomiting is frequently to a certain extent characteristic. It occurs at rather long intervals, and then a very considerable amount is vomited at once. There may be several quarts ejected. The vomitus not infrequently contains bits of food eaten several days previously. Usually vomiting affords the patient temporary relief.

We must have recourse, however, to physical examination in order to be certain about our diagnosis. In many cases, although by no means in all, inspection reveals the contours of a distended stomach through the abdominal walls. The fundus and the greater curvature are most prominent. Sometimes we can observe the peristaltic movements of the stomach, which if not present may perhaps be started up by the mechanical irritation of sudden and repeated palpation. If we administer to the patient a half-drachm each of sodic bicarbonate and tartaric acid, one after the other, as suggested by Frerichs, the consequent distention of the stomach with carbonic-dioxide gas will often render its dimensions much more evident, and we shall also be able to ascertain if the prominence already noticed is really gastric.

By palpation it is often possible to make out the greater curvature and the fundus still better than by inspection, particularly if the muscular coat happens to be contracted. A splashing sound may sometimes be evoked by giving quick, short blows with either hand alternately upon the walls of the stomach. We can hear and feel the contents of the stomach rushing to and fro with great distinctness. This is very characteristic, though not pathognomonic.

To determine the size of the stomach by percussion is so difficult, that percussion is seldom as reliable as inspection and palpation, but now and then it does aid us. The patient must be examined in both the erect and the recumbent posture, and both when the stomach is full and when it is empty. If we introduce

\* In some instances the regurgitated gases have proved inflammable.

about a quart of water into the empty stomach and then find a line of dullness below the navel which was not there before, we have good reason to believe that the organ is dilated. This is Penzoldt's test. Sometimes we are unable to define the limits of the stomach by percussion until we have dilated it with carbonic dioxide; but of course we are to bear in mind that the stomach is in this case expanded beyond its usual limits.

The use of the bougie is valuable. In health the instrument will only penetrate about sixty centimetres, measured from the mouth, while in dilatation it can often be introduced as far as seventy centimetres. Occasionally we may be able to feel the end of the bougie through the lax abdominal walls, as Leube first remarked. In such a case the nearer the point is to a horizontal line joining the two anterior superior spinous processes of the ilium, the greater is the certainty that dilatation exists. Under ordinary conditions the bougie probably does not extend any lower than the level of the umbilicus, if as far as that.

A consideration of the symptoms already enumerated, combined with the above methods of physical examination, will in many cases enable us to diagnose with certainty any considerable dilatation of the stomach; and yet it must be confessed that sometimes quite extensive dilatation may escape observation. In such instances there may be either a partial or complete absence of symptoms suggestive of any serious gastric derangement, so that no careful examination of the organ is made, or the methods of physical examination already mentioned, when employed, yield a negative or ambiguous result. It is true that other methods have been suggested by various authorities to determine the size of the stomach and test the functional capacity of its muscular tissue; but none of these have as yet been generally adopted. Thus Schreiber introduced an India-rubber bag on the end of a catheter, and tried by blowing it up to gain information as to the size and position of the organ. With the same end in view, Rosenbach practiced auscultation of the râles caused by blowing into a catheter, the opening of which was placed at the level of the fluid contained in the stomach.

Other symptoms are mostly analogous to those seen in other severe gastric disorders. The general nutrition becomes gradually so impaired, particularly if there is much vomiting, that the patient may seem like a skeleton. Kussmaul has sometimes observed painful cramps in the flexors of the arms, the calves, and the muscles of the abdomen. These he refers to the abnormal dryness of the muscular tissue. The bowels are almost always very much constipated, mainly as a result of the diminished amount of ingesta which reaches the intestine. The urine is small in amount, and often neutral or alkaline in reaction. The alkaline reaction Quincke believes is more apt to be present while the stomach is being washed out, because in this way the system is deprived of a relatively large amount of acid.

**Course of the Disease and Prognosis.**—The course and duration of the disease are chiefly dependent upon the nature of the original lesion from which the dilatation proceeds. If there is cancerous stenosis of the pylorus, of course the case is hopeless. Cicatricial stenosis with secondary dilatation allows a more favorable prognosis. With proper treatment and a sensible mode of life, the patient may be tolerably comfortable for years; but finally nutrition becomes more and more impaired, and death ensues.

The general course of the disease presents all sorts of vicissitudes. As long as the hypertrophied muscles are able to overcome the abnormal obstruction, there may be no symptoms of importance. Just as in cardiac cases, it is only when compensation becomes disturbed that the results of dilatation are observable. If we can tone up the muscles again, or reduce the work they are called upon to perform to an amount which they are capable of accomplishing, marked relief follows.

Those cases of dilatation which are not due to pyloric stricture have, on the whole, the best prognosis. In milder cases of this kind there may be permanent recovery, provided proper mechanical and dietetic treatment be promptly and persistently employed.

**Treatment.**—Our first aim in treatment should be to relieve the dilated organ of the great amount of material it contains and to avoid new accumulations. If this double effort is successful, we have removed the injurious influences, both mechanical and chemical, which we have seen to maintain and persistently to aggravate the dilatation.

The indication is best met by the "mechanical treatment of dilatation," for which we are so deeply indebted to Kussmaul. This method is beneficial to the chronic catarrh which accompanies the dilatation, or which may even have produced it. We have no direct means of treating stenosis of the pylorus, if it exists, unless possibly by surgical operation. The operative removal of cicatricial stenosis has already been repeatedly performed with success, and it is to be expected that it will come to be practiced more and more.

For emptying and rinsing out the stomach the best means is simple siphonage. A long, soft Nélaton's catheter, supplied with sufficiently large openings on its sides, near its extremity, is joined to a rubber tube of about one metre in length, and to the end of this is fitted a large glass funnel (*vide* Fig. 36). The stomach-tube being introduced and the funnel raised, the entire tube is filled with water and thereupon lowered. Thus siphonage is produced and the contents of the stomach flows out. By alternate raising and lowering of the funnel, combined, of course, with the pouring in of water or soda solution, and the escape of the same again, the stomach may be thoroughly cleansed. It is still more convenient to have a Y-tube of glass fitted to the upper end of the catheter connecting respectively with a reservoir of water and with a slop-jar by rubber tubes, the alternate opening and closing of which will permit water to run into the stomach from the reservoir and then out again into the jar.

The siphon apparatus and the necessary manipulations are so simple that we have had several patients with gastric dilatation who daily washed out their own stomachs. This simple tube has almost completely superseded the regulation stomach-pump. The latter consists of a catheter attached to a syringe which has two openings at its end, one to aspirate and one to allow the escape of liquid. More than once, when this instrument has been employed, a piece of the lining membrane of the stomach has been sucked into the hole at the end of the stomach-tube and torn off. The assumption that the pump empties the stomach more completely than does the siphon is seldom borne out by facts.

We may use pure water for lavage, or, as already mentioned, a one- or two-per-cent. solution of soda or of Carlsbad salts, which may more effectually clear away the mucus. If there is reason to believe that fermentation is particularly active, we may employ a one-per-cent. solution of salicylic acid or a two-per-cent. solution of resorcin. The best time for washing out the stomach is shortly before meals. It is done once or twice a day.

The patient's diet should be carefully regulated. The food should be nourish-

FIG. 36.—Stomach tube, with Hegar's funnel.

ing, easily digestible, and of the least possible bulk. We should therefore try Leube's meat solution, fine shavings of raw beef or ham, soft-boiled eggs, and milk in small amounts, but should avoid vegetables, coarse bread, and the like. In this way we can usually succeed in improving the patient's nutrition decidedly, and the vomiting and sense of gastric oppression as well as other disagreeable symptoms will cease. Whether the improvement will be permanent depends, as has been said, upon the nature of the dilatation and the causal lesion.

In conclusion, we should mention that the attempt has been made to tone up the muscular fibers of the stomach and stimulate them to more vigorous contraction. Energetic faradization and galvanization of the stomach have been recommended. The application may be made through the abdominal walls, or by means of an electrode introduced through a stomach-tube. Nux vomica has also been employed to meet the same indication. The symptomatic treatment of gastric dilatation may employ also all the other remedies mentioned in discussing catarrh of the stomach. It is advantageous to have the patient wear an elastic bandage firmly applied around the abdomen.

## CHAPTER VII.

### NERVOUS DISORDERS OF THE STOMACH.

(*Nervous Dyspepsia. Gastric Neurasthenia.*)

IT very often happens that persons complain of gastric symptoms for which we can assign no objective lesion of the stomach. There is neither any certain indication of any important pathological change, such as dilatation, cancer, or ulcer, nor any history to be obtained of any of the causes of chronic gastric catarrh. On closer study of the cases we find, however, that the stomach symptoms are most strikingly dependent on certain nervous and chiefly psychical conditions. We are therefore justified in describing such affections as nervous diseases of the stomach, and entirely distinct from other affections of that organ.

If we seek to give a more accurate account of the precise nature of these nervous disorders, we must admit, in the first place, that there may be in some cases actual disease of the nerves of the stomach. Thus, for example, cases of pure "nervous cardialgia" occur, the foundation of which is probably a neuralgia of the nerves of the stomach, precisely corresponding to the neuralgias of other sensory nerves. Again, motor derangements are seen which are evidently caused by abnormal excitement of the motor nerves of the stomach, or else of the corresponding nerve-centres. To this class belongs Kussmaul's "peristaltic restlessness of the stomach," characterized by a marked exaggeration of peristalsis, which is both seen and felt through the abdominal walls, is sometimes accompanied by all sorts of gurgling noises, and of which the patient himself is often painfully conscious. Peculiar attacks of nervous vomiting belong in the same category. In many persons they occur from time to time without special cause and with great violence. They may last for hours, or even days, and are often associated with cardialgia, general prostration, and other nervous phenomena. Leyden observed such cases, and described them under the name of "periodical vomiting with paroxysms of gastralgia." The cause of this state is far from clear. Except at the time of the attack there are no symptoms whatever of gastric disease or any other, and we are therefore obliged to assume a "nervous origin" for it. The paroxysm reminds one decidedly of the gastric crisis of tabes dorsalis (*vide* p. 643). It may also be related to migraine (*q. v.*).

If in these cases the vomitus is abnormally sour, we have a condition which Rossbach has named nervous gastroxynsis. Gastroxynsis seems to be associated, therefore, with secretory disturbances, and recalls the above-described acid dyspepsia (*vide* p. 382). There is also a form of persistent, purely nervous vomiting. We have seen it with particular frequency in school children of both sexes, in whom about the only symptom was that they would vomit after every meal.

The varieties already enumerated are not, however, nearly so common as others in which the nervous condition is not so pronounced. The patient complains almost all the time of a train of nervous and dyspeptic sensations, all of which occur mainly after eating, during digestion, and which may therefore be properly classed as nervous dyspepsia. Such a patient will say that he has a sensation of pressure and pain in the stomach after every meal, and that after a few mouthfuls the organ feels full and distended. As a consequence, there are often thoracic oppression and palpitation. The patient frequently suffers also from eructations, which may increase to actual vomiting. All these symptoms may occur in the same way where there is actual gastric disease, particularly gastric catarrh, but in the present instance they are usually associated with other phenomena which indicate their nervous character. In the first place, we may notice that there is often a striking changeableness in their severity. The same patient who to-day complains of severe gastric oppression after a few spoonfuls of soup, will to-morrow, when happy and excited, enjoy a grand dinner without being in the slightest degree reminded of his stomach. This and many other circumstances show most plainly the influence of emotion upon the state of the stomach. We all know how appetite may at once vanish under the influence of violent anger or keen anxiety or lively hope, or any strong emotion, whether pleasurable or the reverse, and that great excitement not infrequently causes vomiting or the like. In the same way, sensitive persons are affected by the slightest psychical influences. And of all such, the most harmful is disquietude with regard to their own bodily condition. The fear that a dish they have eaten may harm them, the constant dread that a serious disease of the stomach is in process of development—such mental disquietude is it which is best calculated to maintain the unhealthy state and gradually to aggravate it. In this way a peculiar subjective hyperæsthesia is developed which feels exquisite "pain" in the stomach when there is really nothing more than the ordinary normal sensation. And, in conclusion, there are developed in the same way certain half-unconscious, half-voluntary movements which produce eructations, vomiting, and the like.

What we desire, therefore, especially to emphasize, is our own conviction that in the large majority of the cases of so-called nervous dyspepsia there is no functional derangement of the nerves of the stomach themselves, but a diseased "psychogenous" excitation of the nerve-centres, the consequences of which are expressed mainly in the domain of the digestive functions. Nervous dyspepsia is only a particular example of that great class of nervous diseases which owe their origin to hypochondriacal conditions of the mind, and which may occur in the most diverse organs of the body. This explains why the gastric symptoms are frequently attended by other nervous phenomena, among which may be mentioned symptoms of increased psychical irritability, headache, pressure in the head, vertigo, and abnormal sensations in the extremities of pain or cold or numbness. There are almost always also some intestinal symptoms. The patient complains of distention of the abdomen, and particularly of irregular and constipated bowels.

Nervous dyspepsia may become a rather serious matter, if the patient's anxiety to avoid errors in diet, and the anorexia occasioned by his uneasy sensations, prevent his taking sufficient nourishment. In this way there may be gradually pro-

duced a considerable or even excessive emaciation, with corresponding debility and weakness. Such a patient may become completely bedridden, and give one at first the impression of severe illness.

In such cases the diagnosis is not always easy, although it can usually be formed upon careful consideration of the whole course of the disease and the character of the patient. Physical examination in nervous dyspepsia is, of course, invariably negative in its results. The epigastrium is often very tender on pressure, and the vertebræ painful. The skin over the stomach is often noticeably insensible to pin-pricks. This fact is a connecting link between nervous dyspepsia and the allied hysterical affections of the stomach. If it is possible to examine the contents of the stomach with the aid of the stomach-tube, the processes of digestion and the secretion of gastric juice are found to be undisturbed. This discovery often has, of course, great diagnostic value, and it holds true at least for most of the cases which rest upon a purely psychical, hypochondriacal basis. If, on the other hand, the patient has not only well-marked nervous symptoms, but also a diminution of the motor power of the stomach, and diminished or (as is not infrequent) increased secretion of acid in the stomach, the diagnosis is usually obscure. These changes may, indeed, depend on purely nervous causes; but still in the individual case it is generally difficult or even impossible to exclude with certainty the simultaneous existence of an actual catarrh or ulcer of the stomach.

In many severe cases it requires long-continued observation of the patient to render a correct diagnosis possible. We may be aided by learning what remedies help and what hurt the patient. This is particularly true where the diagnosis lies between ulcer and nervous dyspepsia, where it may be very difficult, and often, despite careful balancing of all the symptoms, scarcely possible to reach a sure conclusion. A patient with nervous dyspepsia subjected to the strict regimen suitable for ulcer often grows worse and worse, while an opposite course of treatment (*vide infra*) may achieve the most surprising success.

The prognosis depends mainly on the outward circumstances of the patient. If the harmful mental influences or other ætiological factors are persistently active, actual and permanent recovery is hardly to be expected; but if the cause can be removed, complete recovery is not rare, even in what seem to be grave cases. A liability to relapses is, of course, almost always left behind.

**Treatment.**—If nervous dyspepsia has once been diagnosticated, the proper aim of our therapeutic efforts becomes perfectly definite. We must, in the first place, convince the patient that he has no incurable or even dangerous gastric disease, but that, on the contrary, his stomach is perfectly capable of performing its functions in a normal manner. Nothing could be more harmful to a sufferer from nervous dyspepsia than to have his physician manifest great anxiety about treatment, and prescribe a very strict diet. The patient must rather be gradually led to use an abundance of nutritious food. It is in this way alone that he regains a confidence in himself, when he sees that the hearty food does him no harm, that he is gaining flesh, and that the bowels are becoming regular.

Internal remedies are best omitted altogether if the patient has already taken a good deal of medicine. We should particularly warn him against the abuse of purgatives. If we must prescribe something, a bitter tonic is very good, such as tincture of *nux vomica*. Anæmic patients may also take iron. For nervous vomiting and regurgitation the best remedy is bromide of potash. Antipyrin also is sometimes useful.

Those methods of treatment are of great value which are directed to the toning up of the body in general and the nervous system in particular. The patient may go into the country or to the mountains or the seashore. Methodical treatment with cold water is good; in particular, sponging, combined with rubbing of

the trunk and the whole body, almost always gives good results. On the other hand, those health resorts which often do good in the case of organic gastric disease are but seldom beneficial in nervous dyspepsia. Thus, we have frequently seen such patients, who had been sent by their physicians to Carlsbad, return worse rather than better. We have repeatedly found electricity valuable, although we are not prepared to deny that its subjective effect may be of chief importance. Galvanism is applied along the spinal column, and also through the stomach horizontally, one large electrode being placed upon the epigastrium and the other on the back. It is well to reverse the current frequently. Faradization of the abdominal walls is indicated, especially when there is constipation.

We need hardly add that the ætiological factors must not be overlooked. The patient must be warned against useless overexertion, emotional excitement, etc. (Compare the chapter on neurasthenia.)

The main point is to aim at a methodical moral training of the patient. He should learn to feel and to behave like a healthy person. He should regain his self-control, and not allow himself to be upset by every slight psychical shock, whether subjective or coming from without. It is self-evident that this goal is to be attained not by baths and prescriptions, but by correct moral guidance. It is therefore true of nervous dyspepsia, as of all similar neurasthenic conditions, that it is to be cured not by physic but by the physician.

## SECTION V.

### *DISEASES OF THE INTESTINES.*

#### CHAPTER I.

#### INTESTINAL CATARRH.

(*Catarrhal Enteritis.*)

**Ætiology.**—The majority of cases of intestinal catarrh, like gastric catarrh, are due to an abnormal irritation of the mucous membrane of the intestine by its contents. In most cases the irritants are of a mechanical or a chemical nature, and depend upon the quantity and quality of the food taken, which explains why catarrh of the stomach and of the intestine are so often combined with each other. Noxious substances, taken into the system by the ingestion of spoiled food, like spoiled meat, fish, beer, etc., very often play a part in the origin of intestinal catarrh.

To the intestinal catarrhs caused by improper food we may add the toxic catarrhs which are produced by the direct ingestion of poisonous substances into the digestive tract. Severe inflammations of the intestinal mucous membrane arise from poisoning by mineral acids and corrosive alkalies, arsenic, corrosive sublimate, etc. Intestinal catarrh may also arise from the imprudent use of certain drugs, especially active cathartics.

A great many cases of intestinal catarrh are due to infectious influences, including most of the apparently spontaneous catarrhs, and also many, if not all, of the catarrhs attributed to taking cold or getting wet, and, finally, those affections which often develop epidemically or endemically in hot weather, and which we term summer complaint, cholera morbus, etc. Cholera morbus is an especially severe form, and will be described more fully later on. We must also mention

here that intestinal catarrh is very often one symptom of other general infectious diseases, like typhoid, dysentery, septic diseases, or severe malaria.

In a final class of cases intestinal catarrh develops from disturbances of the circulation, which cause a passive hyperæmia of the intestinal mucous membrane. Diseases of the liver and portal vein, and also chronic diseases of the heart and lungs, are the chief affections which produce a stasis in the portal system, and thus an intestinal catarrh; but here the stasis is probably, in most cases, only a predisposing factor in the development of the catarrh, since the action of all other irritants is made easier by the disturbance of the circulation.

The great frequency of intestinal catarrh in both sexes, and at every age, is well known. Children, above all, have a pronounced tendency to diseases of the intestine, so that, by a probable estimate, almost one third of the illnesses of children are to be referred to the intestinal canal. We will give a special description of intestinal catarrh in children on account of this fact.

**Pathological Anatomy.**—The pathological changes in catarrhal inflammation of the intestines are essentially the same as are met with in the inflammation of any other mucous membrane. Redness and swelling of the mucous coat, increased secretion of mucus, and in severe cases purulent products on the surface of the membrane, and a cellular infiltration of the tissue itself, are the well-known processes characteristic of all catarrhal inflammations. The solitary and agminated follicles often swell in follicular catarrh, and may finally become the seat of superficial follicular ulcers. We often find superficial erosions on the rest of the mucous membrane, and in severe cases the so-called catarrhal ulcers.

If the catarrh has lasted a long time, we sometimes find quite a considerable thickening of the mucous membrane, which is due to a hyperplasia of the connective tissue, and which gives an uneven, puffy appearance to the internal surface of the intestine. Circumscribed hyperplasia of the connective tissue may actually lead to the formation of polypi. If the orifices of Lieberkühn's follicles are stopped, we have a cystic degeneration of the follicles from the retention of the intestinal juice.

We very often find, however, a considerable atrophy of the mucous membrane, especially in the chronic intestinal catarrh of children. This atrophy, which has lately been carefully investigated, especially by Nothnagel, affects chiefly the glandular layer of the mucous coat. In place of the glands, which in many parts may wholly disappear, we find connective tissue more or less rich in cells. The atrophy is usually most pronounced in the colon and the lower part of the ileum. The muscular coat may also take part in the atrophy.

Certain peculiarities of catarrh affecting single portions of the intestine will be mentioned later on.

**Symptomatology.**—The symptom by which we chiefly determine an affection of the intestinal canal, and which in the milder cases is often almost the only sign of an intestinal catarrh, is diarrhœa—that is, abnormally frequent stools of a looser consistency than usual; yet, strictly speaking, we should not attribute every diarrhœa to a catarrh of the intestinal mucous membrane, since a large number of influences may directly produce an increased peristalsis and a consequent diarrhœa. Thus, for instance, it is a well-known fact that sudden terror or great anxiety may sometimes cause an obstinate diarrhœa in a very short time. In general nervous and neurasthenic conditions, we sometimes have a chronic diarrhœa which can be due only to abnormal processes of innervation—"nervous diarrhœa." The diarrhœa which may arise immediately after taking cold is also merely the result of abnormally great peristaltic movements excited in a reflex manner. Probably a number of chemical and infectious irritants may also stimu-

late the movements of the intestines, and thus set up a diarrhoea, without causing at the same time a catarrh of the mucous membrane. Practically, however, we can not make a sharp distinction between diarrhoea and intestinal catarrh; and, in most of the diarrhoeas which have lasted for some time, we are certainly right in supposing that there are actual anatomical lesions of the intestine, as well as functional disturbances.

There are two chief factors which cause diarrhoea in intestinal catarrh. In the first place, as has already been intimated, the same injurious substances which cause the catarrh also excite peristalsis. The many products of the abnormal processes of decomposition in the intestine also exert a like influence. Besides the abnormal irritants, however, we ought also to consider an abnormally great irritability of the intestinal walls in catarrh. Thus it happens that the fluid contents of the intestine are expelled by the vigorous peristaltic movements (which the patient himself often feels as a "rumbling in the abdomen"), before the normal consolidation of the faeces is completed by the absorption of water. The food, under normal conditions, passes through the small intestine in two or three hours, and thus the consolidation of the faeces takes place, as is well known, almost exclusively in the colon. We see, therefore, why the diarrhoea owes its origin chiefly to the increased peristalsis of the large intestine; although in many cases the peristaltic action of the small intestine is also increased.

Besides increased peristalsis, another circumstance may perhaps contribute to the diarrhoea, viz., the greater fluidity of the contents of the intestine due to the increased secretion of mucus and the exudation caused by the catarrhal inflammation.

In the intestinal catarrh from passive congestion we must consider still another factor, to explain the thin and watery stools—namely, the diminished absorption of water by the intestine from disturbance of the circulation. In other catarrhs this factor is quite subordinate to increased peristalsis.

The diarrhoeal dejections show a considerable difference in regard to their minor characteristics. Their number varies very much. There are sometimes two or three, and sometimes ten or more, evacuations in the twenty-four hours. The consistency of the stools is pap-like, or almost wholly watery. This is due to the abnormal amount of water in them, amounting to ninety or ninety-five per cent., while the amount in normal stools is about seventy-five per cent. The color of the thin stools in intestinal catarrh is usually bright yellow, but they are sometimes greenish from the admixture of bile pigment, and sometimes slimy (*vide infra*).

In only a part of the cases does microscopic examination give us information as to the extent and intensity of the catarrh. We usually find the remains of the food, muscular fibers, starch-granules, and fat, and also countless bacteria, and often triple phosphates, occasional pus-corpuscles, and cylindrical epithelium—chiefly the constituents which are found in normal stools. Further peculiarities will be mentioned below.

Besides the diarrhoea, there is often, but by no means always, abdominal pain in intestinal catarrh, either continuous, or having the character of the paroxysmal, so-called colicky pains. In catarrh of the rectum there is that constant painful desire to go to stool which we term tenesmus.

Physical examination of the abdomen gives, on the whole, few important results. Sometimes the abdomen is flat, and sometimes there is meteorism. Marked peristaltic action of the intestines often causes gurgling and rumbling noises—*borborygmi*. On palpation, the abdomen is often somewhat sensitive. The peculiar colicky pains, however, are, as a rule, alleviated by external pressure. In rare cases we may detect a fluctuation on palpation, if the intestine contains

much fluid. The results of percussion depend largely upon the fullness of the intestines.

In many cases of simple diarrhoea the general health is practically unaffected, but in other cases of acute intestinal catarrh, especially in the severe infectious forms, the disturbance of the general health may be quite considerable. The patient feels so dull and weak that he stays in bed. We often see a moderate rise of temperature, between 100° and 102° (38°-39° C.). There are very often gastric symptoms also, especially loss of appetite, and vomiting. Other organs are quite rarely affected, except in duodenal catarrh, when the liver is involved (*vide infra*). In acute infectious intestinal catarrhs, there is sometimes an eruption of herpes on the lips. We have repeatedly seen, in severe cases of acute enteritis, marked muscular and articular pains, and even slight but manifest swelling of the joints.

**Different Forms of Intestinal Catarrh.**—Since the intestine is an organ which is only slightly accessible to physical examination during life, and since we can only rarely make a post-mortem examination in the mild diseases of the intestine, our knowledge as to the different forms of enteritis is defective in many respects. In practice we content ourselves in most cases with diagnosing an intestinal catarrh simply from the existence of diarrhoea, without laying much stress upon the special variety; but in many cases some points can be obtained which give information as to the more accurate seat of the catarrh. The distinction between acute and chronic intestinal catarrh is also of practical significance.

Duodenal catarrh can be diagnosed only if it is combined with jaundice. The details regarding it may be found in the chapter on catarrhal jaundice.

Isolated catarrh of the small intestines, of the jejunum and ileum, is probably only of rare occurrence, except when the upper portions of the colon are involved. We can very rarely diagnose it with certainty, but there are a number of factors which permit us to decide that the small intestine is chiefly affected, or at least that it is involved in the disease. In the first place, we may assume an affection of the small intestine, from obvious reasons, in all those cases in which there are also gastric disturbances. It is evident that, in the frequent combination of gastric and intestinal catarrh, the portions of the intestine nearest the stomach will be chiefly affected. Physical examination of the abdomen also gives some indications, since the slight sensitiveness and swelling of the abdomen, as well as the visible abnormal peristaltic action, chiefly affect the middle and lower portions of the abdomen in catarrh of the small intestines, while the analogous symptoms in catarrh of the large intestine affect the lateral and upper portions of the abdomen, corresponding to the anatomical course of the colon. We can not make a sharp distinction, however, in this respect. The results which auscultation and percussion over the abdomen give in regard to the point of origin of the gurgling sounds and the fullness of the loops of intestine are very rarely unequivocal, and hence are of little value in diagnosis.

Careful examination of the stools gives us more information. As has already been said, we need have no diarrhoea in a catarrh confined to the small intestines, since diarrhoea is due only to the increased peristalsis of the large intestine; hence diarrhoea is absent, for example, in most cases of duodenal catarrh (catarrhal jaundice). In extensive isolated catarrh of the small intestines the firm stools passed may, however, be regarded as pathological, because, on microscopic examination, they appear intimately mixed with little lumps of hyaline mucus (Nothnagel). As a rule, of course, catarrh of the small intestines is combined with a catarrh of the upper portion of the large intestine. Then we have a diarrhoea, but the thin stools show some peculiarities which point to an implication of the small intestines. As a result of the increased peristalsis of the small intestines, we find certain constituents in the stools which are normally contained in the small intes-

tines, but which under normal conditions are no longer to be met with in the *feces* in the large intestine. We find here, in the first place, undigested constituents of the food, large masses of muscular fiber, or even fragments of meat which may be recognized by the naked eye, and also starch and fat. Of course the opposite hypothesis does not hold good, that, if we find a large amount of the undigested portions of the food in the stools, it must necessarily always point to a catarrh of the small intestines, since the digestion may be impaired by other circumstances, like fever or anæmia, and increased peristalsis of the intestines, from any cause, must result in the same symptoms. A diarrhoea, where the thin stools contain a very large amount of undigested particles of food which can be recognized by the naked eye, was formerly called *lientery*, and the term is still occasionally used.

If the stools contain bile in addition to some portions of the food, it is to a certain degree characteristic of catarrh of the small intestines. Under normal conditions the contents of the small intestines alone show Gmelin's test for bile-pigment, while the contents of the large intestine, and also the normal stools, do not. In intestinal catarrh, with increased peristalsis of the small and large intestines, there is, however, often quite a large admixture of still undecomposed bile-pigment. The green stools which are so often seen in the diarrhoea of children, and more rarely in that of adults, are also well known. Such stools usually show a marked color reaction with nitric acid. In other cases we find only certain constituents of the stools stained with bile—a fact to which Nothnagel has called special attention. Yellow pigmented bits of mucus and cylindrical epithelium, and round cells stained with bile, are especially characteristic of the diarrhoea of catarrh of the small intestines.

Catarrh of the large intestine is probably present in every diarrhoea, as has been repeatedly stated, inasmuch as the thin stools can be explained only by an increased peristalsis of the large intestine; but in a number of cases we have symptoms which point especially to a disease of the large intestine, particularly of its lower portion.

Physical examination of the abdomen should show changes, like swelling, sensitiveness to pressure, etc., chiefly in the lateral portions, corresponding to the course of the colon; but this is rather a theoretical hypothesis than a sign of practical value. We can not definitely affirm, either, that "colicky pains" are characteristic of catarrh of the large intestine alone. The condition of the stools, however, is of importance. In the first place, we may note that, if the stools contain many masses of mucus which may be recognized by the naked eye, it is of diagnostic significance. As we have seen above, the stools in catarrh of the small intestines also contain mucus, but it is intimately mixed with the other constituents of the *feces*, and hence it can usually be recognized only by the microscope. In catarrh of the large intestine, however, the mucus rather adheres to the outside of the other constituents, and is often present in large masses visible to the naked eye. If the catarrh affects the lower part of the large intestine chiefly, it may be that the intestinal contents are already formed into firm lumps, which may sometimes be wholly or partly inclosed in a layer of mucus. In acute catarrh of the lowest part of the large intestine the evacuations are sometimes composed chiefly of pure mucus, with a greater or less admixture of pus, as is seen chiefly in the "catarrhal flux" (see the chapter on dysentery). The more the rectum is involved in the inflammation, the worse is that painful feeling of tension and pressure at the anus during and after the evacuation, which we term *tenesmus*.

Isolated inflammation of the rectum (*proctitis*) is, at least in part, directly accessible to examination by the finger or by the speculum. Painful *tenesmus* and an admixture of mucus, and especially of pus in the stools, are the chief symp-

toms of the disease. In most cases, however, we have to do, not with a primary disease, but with a secondary catarrh of the rectal mucous membrane, as a result of different morbid conditions in the vicinity of the rectum, or of new growths, syphilitic processes, etc., in the rectum itself. Periproctitis (ischio-rectal abscess) belongs to the domain of surgery, and can not be described here.

Intestinal catarrh is divided into an acute and a chronic form.

In the acute intestinal catarrhs, excluding the toxic inflammations, we class simple diarrhoea, which usually passes off in a few days, and the severe enteritis, which is probably usually infectious, and which is attended by a marked disturbance of the general health, by fever, and sometimes by gastric symptoms also, as well as by herpes, by occasional slight albuminuria, by articular pains, etc. It lasts from three to ten days. Cholera morbus (*vide infra*) is to be regarded as a special form of acute infectious inflammation of the gastric and intestinal mucous membranes.

Chronic intestinal catarrh either comes from an acute disease of the intestinal mucous membrane, or it gradually develops independently. In adults it is by no means a frequent disease, at least as regards pronounced cases, and is much rarer, for example, than chronic gastric catarrh; but we have already mentioned that it is very common in practice among children.

[Chronic intestinal catarrh is much more common in the southern than in the northern portions of our country. It was the great scourge of camps during our late civil war, and there are many men alive to-day, pensioned and unpensioned, who have never recovered from the diarrhoea contracted during their army life.]

In regard to the ætiology and symptomatology, much the same may be said of chronic catarrh which we have learned to recognize in considering acute catarrh. In regard to ætiology we must note, in adults, chiefly the intestinal affections remaining after an attack of an acute disease, like dysentery, severe malaria, or typhoid. Among the most prominent symptoms are the abnormal evacuations, usually alternating between diarrhoea and constipation, but sometimes showing persistent constipation, due chiefly to the atrophy of the muscular coat and the disturbance of the nervous apparatus. We must also mention, as a prominent symptom, the secondary disturbances of the general nutrition, like emaciation and anæmia. In regard to peculiarities in the character of the stools, we must refer to what has been said above. As chronic catarrh of the large intestine is far commoner than chronic catarrh of the small intestines, we very often find large amounts of mucus in the stools. Special mention must here be made of a particular form of chronic catarrh of the large intestine, in which large pieces of membrane and complete mucous casts of the intestinal canal are evacuated.

This peculiar condition, of which we have seen several cases, affects women most frequently, but it is also met with in men. The disease is almost always associated with obstinate constipation. Either at the same time with hard scybala, or quite independently, large masses of this membrane are from time to time evacuated, and the passage of them is often associated with quite severe colic. These masses, as the microscope shows, consist of mucus, and often contain also much cylindrical epithelium, and more rarely a few round cells and occasional crystals of cholesterine and triple phosphate. The general nutrition sometimes suffers but little, but in other cases quite a good deal. We very often see in women, at the same time, all sorts of hysterical and nervous symptoms. The disease, which is termed membranous enteritis, desquamative catarrh of the large intestine, or mucous colic (*colica mucosa*), may last for years. No thorough examination has yet been made into the ætiology and pathology of the disease, but it is most probable that the intestinal mucus collects into the membranous for-

mations above described in the bottom of the longitudinal folds of the spasmodically contracted large intestine (Marchand).

**Treatment.**—Most of the milder cases of acute intestinal catarrh need only a dietetic treatment. If the patient avoids all injurious substances for a few days, he recovers completely. The different gruels, like barley and oatmeal gruel, and also weak broths and thoroughly toasted bread, or the German *zwieback*, are generally regarded as the most suitable food. The coarser vegetables and fruits, fat meat and brown bread, are to be avoided as much as possible. In other respects we may refer to the dietetic rules laid down under the treatment of chronic gastric catarrh.

It is also an important rule, confirmed by much experience, to keep the abdomen warm. Children should always stay in bed, and adults should do so, at least in all severe cases. It is a good plan, particularly in children, to protect the abdomen from cold by a flannel band.

In many of the mild cases it is scarcely necessary to use internal remedies. Gum mixture (P. G.) or almond mixture is a good prescription if there is no special indication, but in severe cases further medication may be proper. If we have reason to suspect some irritating ingesta or a collection of faeces as a cause of the intestinal catarrh, a cathartic acts favorably at the beginning of the treatment, in spite of the existence of diarrhoea. Our best cathartic in such cases is castor-oil or calomel. In all those cases where many thin dejections point to a greatly increased peristalsis of the intestine, we use astringents, especially opium, which we give in the form of the simple tincture or the wine in doses of ten or fifteen drops, one to three times a day; or as a powder, half a grain to a grain (grm. 0·03 to 0·05) of opium with a grain (grm. 0·05) of sugar, two or three times a day. It is also recommended to combine the opium with some mucilaginous vehicle, as 2 parts of laudanum to 150 of gum mixture or decoction of salep (P. G.), a teaspoonful every two or three hours.

Besides opium, the different astringents are used in the treatment of intestinal catarrh, especially tannic acid, acetate of lead, logwood, columbo, catechu, and many others. These remedies are often given combined with opium, as in the following prescriptions:

- R Opii..... gr. ss. (grm. 0·03);  
 Acidi tannici..... gr. j. ( " 0·05);  
 Sacchari albi..... gr. j. ( " 0·05). M.  
 S. As a powder two or three times a day.  
 R Decoct. radicis calumbæ.....(1-15) ℥ v. (grm. 150·0);  
 Extract. opii..... gr. j. ( " 0·05);  
 Syrup. aurantii..... ℥ ss. ( " 15·0). M.  
 S. Tablespoonful every two hours.

Good results, particularly in chronic cases, are sometimes obtained from the administration of bismuth. Either the subnitrate or the salicylate may be given in powders containing seven or eight grains (0·4-0·5).

If there is severe colic, opium, or, under some circumstances, an injection of morphine is the best remedy. In milder cases it is sufficient to apply warmth to the abdomen, by warm poultices or hot towels. The colic, however, often depends upon the presence of old faecal masses in the intestine, when it is necessary to prescribe a cathartic, like castor-oil.

In all cases where the symptoms point to a more intense disease of the large intestine, local treatment may be employed. This is chiefly of importance in the treatment of chronic intestinal catarrh which is situated mainly in the large

here that intestinal catarrh is very often one symptom of other general infectious diseases, like typhoid, dysentery, septic diseases, or severe malaria.

In a final class of cases intestinal catarrh develops from disturbances of the circulation, which cause a passive hyperæmia of the intestinal mucous membrane. Diseases of the liver and portal vein, and also chronic diseases of the heart and lungs, are the chief affections which produce a stasis in the portal system, and thus an intestinal catarrh; but here the stasis is probably, in most cases, only a predisposing factor in the development of the catarrh, since the action of all other irritants is made easier by the disturbance of the circulation.

The great frequency of intestinal catarrh in both sexes, and at every age, is well known. Children, above all, have a pronounced tendency to diseases of the intestine, so that, by a probable estimate, almost one third of the illnesses of children are to be referred to the intestinal canal. We will give a special description of intestinal catarrh in children on account of this fact.

**Pathological Anatomy.**—The pathological changes in catarrhal inflammation of the intestines are essentially the same as are met with in the inflammation of any other mucous membrane. Redness and swelling of the mucous coat, increased secretion of mucus, and in severe cases purulent products on the surface of the membrane, and a cellular infiltration of the tissue itself, are the well-known processes characteristic of all catarrhal inflammations. The solitary and agminated follicles often swell in follicular catarrh, and may finally become the seat of superficial follicular ulcers. We often find superficial erosions on the rest of the mucous membrane, and in severe cases the so-called catarrhal ulcers.

If the catarrh has lasted a long time, we sometimes find quite a considerable thickening of the mucous membrane, which is due to a hyperplasia of the connective tissue, and which gives an uneven, puffy appearance to the internal surface of the intestine. Circumscribed hyperplasia of the connective tissue may actually lead to the formation of polypi. If the orifices of Lieberkühn's follicles are stopped, we have a cystic degeneration of the follicles from the retention of the intestinal juice.

We very often find, however, a considerable atrophy of the mucous membrane, especially in the chronic intestinal catarrh of children. This atrophy, which has lately been carefully investigated, especially by Nothnagel, affects chiefly the glandular layer of the mucous coat. In place of the glands, which in many parts may wholly disappear, we find connective tissue more or less rich in cells. The atrophy is usually most pronounced in the colon and the lower part of the ileum. The muscular coat may also take part in the atrophy.

Certain peculiarities of catarrh affecting single portions of the intestine will be mentioned later on.

**Symptomatology.**—The symptom by which we chiefly determine an affection of the intestinal canal, and which in the milder cases is often almost the only sign of an intestinal catarrh, is diarrhoea—that is, abnormally frequent stools of a looser consistency than usual; yet, strictly speaking, we should not attribute every diarrhoea to a catarrh of the intestinal mucous membrane, since a large number of influences may directly produce an increased peristalsis and a consequent diarrhoea. Thus, for instance, it is a well-known fact that sudden terror or great anxiety may sometimes cause an obstinate diarrhoea in a very short time. In general nervous and neurasthenic conditions, we sometimes have a chronic diarrhoea which can be due only to abnormal processes of innervation—"nervous diarrhoea." The diarrhoea which may arise immediately after taking cold is also merely the result of abnormally great peristaltic movements excited in a reflex manner. Probably a number of chemical and infectious irritants may also stimu-

late the movements of the intestines, and thus set up a diarrhoea, without causing at the same time a catarrh of the mucous membrane. Practically, however, we can not make a sharp distinction between diarrhoea and intestinal catarrh; and, in most of the diarrhoeas which have lasted for some time, we are certainly right in supposing that there are actual anatomical lesions of the intestine, as well as functional disturbances.

There are two chief factors which cause diarrhoea in intestinal catarrh. In the first place, as has already been intimated, the same injurious substances which cause the catarrh also excite peristalsis. The many products of the abnormal processes of decomposition in the intestine also exert a like influence. Besides the abnormal irritants, however, we ought also to consider an abnormally great irritability of the intestinal walls in catarrh. Thus it happens that the fluid contents of the intestine are expelled by the vigorous peristaltic movements (which the patient himself often feels as a "rumbling in the abdomen"), before the normal consolidation of the faeces is completed by the absorption of water. The food, under normal conditions, passes through the small intestine in two or three hours, and thus the consolidation of the faeces takes place, as is well known, almost exclusively in the colon. We see, therefore, why the diarrhoea owes its origin chiefly to the increased peristalsis of the large intestine; although in many cases the peristaltic action of the small intestine is also increased.

Besides increased peristalsis, another circumstance may perhaps contribute to the diarrhoea, viz., the greater fluidity of the contents of the intestine due to the increased secretion of mucus and the exudation caused by the catarrhal inflammation.

In the intestinal catarrh from passive congestion we must consider still another factor, to explain the thin and watery stools—namely, the diminished absorption of water by the intestine from disturbance of the circulation. In other catarrhs this factor is quite subordinate to increased peristalsis.

The diarrhoeal dejections show a considerable difference in regard to their minor characteristics. Their number varies very much. There are sometimes two or three, and sometimes ten or more, evacuations in the twenty-four hours. The consistency of the stools is pap-like, or almost wholly watery. This is due to the abnormal amount of water in them, amounting to ninety or ninety-five per cent., while the amount in normal stools is about seventy-five per cent. The color of the thin stools in intestinal catarrh is usually bright yellow, but they are sometimes greenish from the admixture of bile pigment, and sometimes slimy (*vide infra*).

In only a part of the cases does microscopic examination give us information as to the extent and intensity of the catarrh. We usually find the remains of the food, muscular fibers, starch-granules, and fat, and also countless bacteria, and often triple phosphates, occasional pus-corpuscles, and cylindrical epithelium—chiefly the constituents which are found in normal stools. Further peculiarities will be mentioned below.

Besides the diarrhoea, there is often, but by no means always, abdominal pain in intestinal catarrh, either continuous, or having the character of the paroxysmal, so-called colicky pains. In catarrh of the rectum there is that constant painful desire to go to stool which we term tenesmus.

Physical examination of the abdomen gives, on the whole, few important results. Sometimes the abdomen is flat, and sometimes there is meteorism. Marked peristaltic action of the intestines often causes gurgling and rumbling noises—*borborygmi*. On palpation, the abdomen is often somewhat sensitive. The peculiar colicky pains, however, are, as a rule, alleviated by external pressure. In rare cases we may detect a fluctuation on palpation, if the intestine contains

much fluid. The results of percussion depend largely upon the fullness of the intestines.

In many cases of simple diarrhoea the general health is practically unaffected, but in other cases of acute intestinal catarrh, especially in the severe infectious forms, the disturbance of the general health may be quite considerable. The patient feels so dull and weak that he stays in bed. We often see a moderate rise of temperature, between  $100^{\circ}$  and  $102^{\circ}$  ( $38^{\circ}$ - $39^{\circ}$  C.). There are very often gastric symptoms also, especially loss of appetite, and vomiting. Other organs are quite rarely affected, except in duodenal catarrh, when the liver is involved (*vide infra*). In acute infectious intestinal catarrhs, there is sometimes an eruption of herpes on the lips. We have repeatedly seen, in severe cases of acute enteritis, marked muscular and articular pains, and even slight but manifest swelling of the joints.

**Different Forms of Intestinal Catarrh.**—Since the intestine is an organ which is only slightly accessible to physical examination during life, and since we can only rarely make a post-mortem examination in the mild diseases of the intestine, our knowledge as to the different forms of enteritis is defective in many respects. In practice we content ourselves in most cases with diagnosing an intestinal catarrh simply from the existence of diarrhoea, without laying much stress upon the special variety; but in many cases some points can be obtained which give information as to the more accurate seat of the catarrh. The distinction between acute and chronic intestinal catarrh is also of practical significance.

Duodenal catarrh can be diagnosed only if it is combined with jaundice. The details regarding it may be found in the chapter on catarrhal jaundice.

Isolated catarrh of the small intestines, of the jejunum and ileum, is probably only of rare occurrence, except when the upper portions of the colon are involved. We can very rarely diagnose it with certainty, but there are a number of factors which permit us to decide that the small intestine is chiefly affected, or at least that it is involved in the disease. In the first place, we may assume an affection of the small intestine, from obvious reasons, in all those cases in which there are also gastric disturbances. It is evident that, in the frequent combination of gastric and intestinal catarrh, the portions of the intestine nearest the stomach will be chiefly affected. Physical examination of the abdomen also gives some indications, since the slight sensitiveness and swelling of the abdomen, as well as the visible abnormal peristaltic action, chiefly affect the middle and lower portions of the abdomen in catarrh of the small intestines, while the analogous symptoms in catarrh of the large intestine affect the lateral and upper portions of the abdomen, corresponding to the anatomical course of the colon. We can not make a sharp distinction, however, in this respect. The results which auscultation and percussion over the abdomen give in regard to the point of origin of the gurgling sounds and the fullness of the loops of intestine are very rarely unequivocal, and hence are of little value in diagnosis.

Careful examination of the stools gives us more information. As has already been said, we need have no diarrhoea in a catarrh confined to the small intestines, since diarrhoea is due only to the increased peristalsis of the large intestine; hence diarrhoea is absent, for example, in most cases of duodenal catarrh (catarrhal jaundice). In extensive isolated catarrh of the small intestines the firm stools passed may, however, be regarded as pathological, because, on microscopic examination, they appear intimately mixed with little lumps of hyaline mucus (Nothnagel). As a rule, of course, catarrh of the small intestines is combined with a catarrh of the upper portion of the large intestine. Then we have a diarrhoea, but the thin stools show some peculiarities which point to an implication of the small intestines. As a result of the increased peristalsis of the small intestines, we find certain constituents in the stools which are normally contained in the small intes-

tines, but which under normal conditions are no longer to be met with in the *feces* in the large intestine. We find here, in the first place, undigested constituents of the food, large masses of muscular fiber, or even fragments of meat which may be recognized by the naked eye, and also starch and fat. Of course the opposite hypothesis does not hold good, that, if we find a large amount of the undigested portions of the food in the stools, it must necessarily always point to a catarrh of the small intestines, since the digestion may be impaired by other circumstances, like fever or *anæmia*, and increased peristalsis of the intestines, from any cause, must result in the same symptoms. A diarrhoea, where the thin stools contain a very large amount of undigested particles of food which can be recognized by the naked eye, was formerly called *lientery*, and the term is still occasionally used.

If the stools contain bile in addition to some portions of the food, it is to a certain degree characteristic of catarrh of the small intestines. Under normal conditions the contents of the small intestines alone show Gmelin's test for bile-pigment, while the contents of the large intestine, and also the normal stools, do not. In intestinal catarrh, with increased peristalsis of the small and large intestines, there is, however, often quite a large admixture of still undecomposed bile-pigment. The green stools which are so often seen in the diarrhoea of children, and more rarely in that of adults, are also well known. Such stools usually show a marked color reaction with nitric acid. In other cases we find only certain constituents of the stools stained with bile—a fact to which Nothnagel has called special attention. Yellow pigmented bits of mucus and cylindrical epithelium, and round cells stained with bile, are especially characteristic of the diarrhoea of catarrh of the small intestines.

Catarrh of the large intestine is probably present in every diarrhoea, as has been repeatedly stated, inasmuch as the thin stools can be explained only by an increased peristalsis of the large intestine; but in a number of cases we have symptoms which point especially to a disease of the large intestine, particularly of its lower portion.

Physical examination of the abdomen should show changes, like swelling, sensitiveness to pressure, etc., chiefly in the lateral portions, corresponding to the course of the colon; but this is rather a theoretical hypothesis than a sign of practical value. We can not definitely affirm, either, that "*colicky pains*" are characteristic of catarrh of the large intestine alone. The condition of the stools, however, is of importance. In the first place, we may note that, if the stools contain many masses of mucus which may be recognized by the naked eye, it is of diagnostic significance. As we have seen above, the stools in catarrh of the small intestines also contain mucus, but it is intimately mixed with the other constituents of the *feces*, and hence it can usually be recognized only by the microscope. In catarrh of the large intestine, however, the mucus rather adheres to the outside of the other constituents, and is often present in large masses visible to the naked eye. If the catarrh affects the lower part of the large intestine chiefly, it may be that the intestinal contents are already formed into firm lumps, which may sometimes be wholly or partly inclosed in a layer of mucus. In acute catarrh of the lowest part of the large intestine the evacuations are sometimes composed chiefly of pure mucus, with a greater or less admixture of pus, as is seen chiefly in the "*catarrhal flux*" (see the chapter on dysentery). The more the rectum is involved in the inflammation, the worse is that painful feeling of tension and pressure at the anus during and after the evacuation, which we term *tenesmus*.

Isolated inflammation of the rectum (*proctitis*) is, at least in part, directly accessible to examination by the finger or by the speculum. Painful *tenesmus* and an admixture of mucus, and especially of pus in the stools, are the chief symp-

The anatomical changes of the intestinal mucous membrane in children who die of "chronic intestinal catarrh" are, as a rule, only slightly marked, and contrast, in their apparent insignificance, with the severe intestinal symptoms observed during life. Probably here also the toxic influences of the matters abnormally generated in the intestine, play a more important part than do the anatomical changes. We must remember, however, that most catarrhal conditions are hard to recognize in the cadaver because of the disappearance of the hyperæmia. Sometimes the swelling of the follicles is especially marked—follicular catarrh. Follicular ulcers are also seen. In other cases the atrophy of the mucous membrane, which is often seen after chronic catarrhs, is the chief lesion. Chronic thickening and swelling of the mucous membrane is of rarer occurrence. In most of the severe cases the large intestine, and also the lower portion of the ileum, are the chief seat of the changes. We often find a swelling of the mesenteric lymph-glands, and also a fatty liver. In the lungs extensive atelectases or nodules of catarrhal pneumonia often develop as a result of the imperfect respiration.

The symptoms of chronic intestinal catarrh are, in the first place, those due directly to the intestinal trouble, and, secondly, the quite rapid disturbance of the child's general nutrition.

The condition of the stools is the most important intestinal symptom. The normal dejection in children until they are weaned is of the color of the yolk of an egg, of a rather pasty consistency, and of a faintly sour smell. In intestinal catarrh the stools are more frequent, six or seven, and even more, a day. They are thinner, more watery, contain large flakes and lumps of undigested bits of casein and other remains of food, and smell badly. They very often have a green color, or acquire it on standing. According to recent French investigations (Lesage), this green coloring matter is generated by a specific kind of bacilli, which are also to be regarded as the pathogenic cause of intestinal catarrhs with green evacuations. We may find admixtures of mucus, sometimes in the form of the so-called "sago grains," especially in catarrh of the large intestine. In the severe forms we often find pus-corpuscles and epithelium under the microscope, besides remains of the food. The stools may contain small amounts of blood.

There is no definite distinction in regard to the dejections in catarrh of the large and of the small intestines. On the whole, the rule holds that, in catarrh of the small intestines chiefly, the stools are larger, they are passed with more wind or gas, and show a more uniform consistency; while in catarrh of the large intestine they are smaller but more frequent, ten or twenty a day, are passed noiselessly, are associated with tenesmus, and show a different consistency in their various parts, partly normal, partly thin, partly slimy, etc. Examination of the abdomen is in so far of importance that, in general, in catarrh of the small intestines the abdomen is much swollen, while in catarrh of the large intestine it is often deeply sunken.

We often find disturbances in the stomach, vomiting, eructations, etc., as well as trouble in the intestines. There may be thrush in the mouth, or the development of aphthous ulcers.

In almost all long-continued cases, however, the general disturbance of nutrition, the atrophy (*athrepsia*) of the child, takes the first place in the picture of the disease. The muscles become shriveled and flabby, and the whole body finally becomes so much emaciated that the pale, dry skin hangs in broad folds and wrinkles about the bones, whose prominences are everywhere visible. The face is sharp, and has an aged expression from the many little folds of the skin. The eyes are dull, lusterless, and wide open; the voice is merely a low, hoarse whimper. The abdomen is deeply sunken, or in some cases it is swollen by meteorism,

in peculiar contrast to the emaciation elsewhere; and its surface is traversed by bluish veins.

From this sad picture, unfortunately so frequently seen in practice among children, we can usually recognize the condition of things at the first glance, for by far the larger part of the cases called "pedatrophies" are due to chronic digestive disturbances. Very often it is combined with rachitic changes in the bones, of whose occurrence we shall speak further in the description of rachitis. Tubercular changes, too, are often found in the cadaver, especially in the lungs and the bronchial and mesenteric lymph-glands. In such cases, of course, the tuberculosis is usually to be regarded as the main disease, upon which the intestinal affection, which may be simple or even tubercular, has developed secondarily. During life tuberculosis in little atrophic children may very easily be overlooked.

If we would give a full account of the treatment of the atrophic conditions in children due to digestive disturbances, we must include in our consideration the entire hygiene and care of children in health and disease, for all children's physicians are united in the opinion that, as the cause of most intestinal diseases in children is to be found in improper feeding, so recovery from existing digestive disturbances can take place primarily only by a corresponding proper and judicious feeding. In what follows we can refer only to the most important principles and general points which are here to be considered.

The only proper and natural food for a child in its first year is breast-milk. All dyspeptic conditions are much rarer in children who are nursed than in bottle-fed children, and, when they do occur in children at the breast, they often are only of brief duration. They are then to be referred usually to certain disturbances in the mother, such as disease, insufficient diet, or severe mental excitement. The return of menstruation or a new pregnancy has sometimes an unfavorable influence on the character of the milk. Finally, we may mention that in spite of the best of milk, if the breast is given irregularly and too frequently, it may cause anomalies of digestion in nursing children.

Most of these slight disturbances may easily be readjusted, but sometimes it happens that, without any discoverable reason, the milk of a wet-nurse "does not agree" with the child. Then we must change the nurse. The atrophic conditions which develop and progress in children, in spite of plenty of normal food, are usually due, not to simple digestive disturbances, but to deep-seated, general, constitutional diseases like tuberculosis, or syphilis.

The great majority of cases of chronic intestinal catarrh and chronic atrophy are found, as we have said, in bottle-fed children. The first question which every physician should ask a mother who brings him such a child for treatment, must therefore refer to the sort of feeding which the child has. If the mother, for any reason, can not nurse it herself, and if the bottle-fed child has digestive disturbances, we must invariably consider, in the first place, the possibility of procuring a wet-nurse. Feeding by the milk of a wet-nurse is a remedy which, at least in many cases, by saving the child's life, repays the many annoyances and quite large expense which a wet-nurse causes. We must tell the parents this, and represent to them, without reserve, the great dangers which threaten the life of every bottle-fed baby. Complete, and sometimes even quite rapid, recovery may be obtained through a wet-nurse, even in cases of severe chronic intestinal catarrh, where atrophy and weakness are already very far advanced.

Often, however, it is impossible to hire a wet-nurse, especially in the poorer classes of society. We must continue bottle-feeding, and these are the cases where chronic intestinal catarrh demands the greatest number of victims; yet even here the physician can always do much good by instructing the parents.

The best substitute for mother's milk is cow's milk. This must be as fresh as

possible, and is given boiled. The Soxhlet apparatus for preparing the milk is rather troublesome, but very appropriate and advantageous. By its means the milk is completely sterilized. One part of the milk must be diluted, according to its quality, with two or three parts of boiled water in the first months, in children from four to six months old with equal parts of water, and in older children with about half as much water. From nine to twelve months, the child may have undiluted milk. In general we give the milk warmed to about 85° (28° C.), but children with gastro-intestinal catarrh often bear cold milk, given in small amounts, better than warm. Among the special additions to the milk, by which physicians have tried to make cow's milk more like human milk, we may mention as occasionally advantageous sugar of milk, as much as will go on the point of a small knife, added to each portion of milk given, and soda, a tablespoonful of a one- or two-per-cent. solution to a pint (half a litre) of milk. The much-practiced dilution of milk with salep, oat-meal, and barley waters is always injudicious, and it should be a principle, especially with children under three months, to avoid entirely any starchy food. It is not a bad plan to add veal-broth to the milk, as it is sometimes well borne even by weak children.

Cow's milk, properly diluted, is better for children with chronic intestinal catarrh, in many cases, than any other food. In acute digestive disturbances, however, it is sometimes advisable to omit the milk entirely for a few days, and give instead of it only a little mucilaginous drink like decoction of salep. In chronic dyspepsia we must first try good cow's milk. If the milk is not well borne, if the diarrhoea increases, and if the child becomes still more emaciated, we may try to get milk from another and better source; but it often happens that either we can not procure good milk, or that the child can not bear even the best cow's milk. We are then obliged to have recourse to one of the many "artificial foods" and "substitutes for mothers' milk" in the market. We can not here go into particulars concerning these. Each of these preparations has occasional good results to show, but none of them has an uncontested pre-eminence over the rest. We will mention the preparations most in use at present, of whose value in individual cases we have convinced ourselves: Swiss condensed milk, Nestlé's and Frerich's infants' foods, Biedert's cream mixture, and Liebig's soup. Almost every physician has his special favorite preparation, which in his own personal experience has done him relatively the best service.

If we keep fast to the principle that every intestinal catarrh in children is to be treated in the first place by a judicious regulation of the diet, in many cases we shall not have to use any drugs. These may be of service only when we have also carried out the dietetic measures which are specially necessary.

Calomel has obtained the greatest reputation in the treatment of intestinal catarrh in children. It deserves to be tried in fresh cases, in doses of  $\frac{1}{2}$  to  $\frac{1}{4}$  of a grain (grm. 0.005-0.01) in powder. If the diarrhoea lasts a long time, we may very well use opiates, although with great caution. The combination of calomel and opium often does good service.

R Calomel ..... gr.  $\frac{1}{2}$  (grm. 0.01);  
 Extracti opii ..... gr.  $\frac{1}{2}$  ( " 0.002);  
 Pulv. acaciæ ..... gr. ss ( " 0.03).  
 M. et ft. pulv.

Sig.: One such powder, three or four times a day.

With little children we may put two to four drops of laudanum in three ounces (grm. 100) of liquid, like gum mixture, salep decoction, muriatic-acid mixture, etc., and give a dessertspoonful of this every two or three hours.

Many attempts have been made to check the abnormal processes of decomposition in the intestine by prescribing remedies which possess antiseptic and antizymotic properties. Creasote has been warmly recommended by many, four to six drops in two ounces (grm. 50) of water with half an ounce (grm. 15) of syrup, a teaspoonful every two hours. Other drugs used for the same purpose are naphthalin, one-half- to one-per-cent. solution of dilute muriatic acid in water, and one-per-cent. solution of chloral in water. A prescription for naphthalin is as follows:

R Naphthalin.....0·5 to 1·0;  
 Mucilag. acaciae,  
 Aquæ destillat.....âā 40·0;  
 Ol. menthæ pip.....gt. j.  
 M. Sig.: Shake. Teaspoonful every two hours.

If the stools have a green color, it is said that lactic acid is especially beneficial. A teaspoonful of a two-per-cent. solution may be given fifteen minutes after every meal.

A number of other remedies, "astringents," are given to act directly on the diseased mucous membrane. Those most to be recommended in chronic diarrhœa are subnitrate of bismuth, one or two grains (grm. 0·05-0·1) four to six times a day, which may be combined with opium, nitrate of silver (1 to 2,000 solution), alum (1 to 200 solution), guarana, five to fifteen grains (grm. 0·3-1·0), three times a day, and many others.

If a large amount of mucus in the stools points to a catarrh of the large intestine, we may sometimes employ irrigation of the colon with excellent results. We inject the fluid, one-per-cent. solution of tannin or alum, or solution of acetate of lead (1 to 3 to 1,000), once or twice a day. The amount of fluid to be introduced at once, by a Hegar's funnel, with a gum-elastic catheter, may reach one or two pints (half a litre to a litre).

In conclusion, we must mention the advantage of daily warm baths in atrophic children. We often order some special "strengthening" additions to the bath-water, such as salt, iron, or sweet-flag.

[In view of the great importance of this malady, it seems desirable to remark on one or two points.

In the first place, prophylactic measures are deducible directly from the ætiology. No child should be kept in a large city in summer, if it can be provided for at the sea-shore or in the country. The vast number who must perforce remain are to be kept under the best general hygienic conditions possible. Mothers should be encouraged to take their children to the relatively pure air of the public parks as much as they can. The relation between diet and the diarrhœa of children should be dwelt upon whenever there is opportunity.

The establishment of boards of health has done much, and will do more, to check the ravages of summer diarrhœa.

Great advances have been made in the artificial digestion of cow's milk within a few years. By the aid of the preparations of Fairchild Bros. & Foster the caseine is digested in part, and the remaining portions coagulate in light flocculi; at the same time no appreciable taste is imparted to the milk, provided that a moderate amount of care is exercised. The importance of preventing the formation of large, firm curds has long been recognized, and an older means of attaining this end was mechanically to separate the curd by adding to the milk a barley or other similar water-gruel.

Mellin's, Horlick's, and Ridge's foods also deserve mention in this connection.

The quantities of food, as well as the frequency with which it is given, must be determined in each case.

The system of milk inspection which has come into vogue of late years in many places does much to improve the milk supply, as does also an improved method of transportation. But still, especially during the summer heat, a really fresh and pure article is nearly impossible of attainment by the poorer classes in large cities, and it is these classes which swell the mortality from infantile diarrhoea. For them, in particular, the modern simple and inexpensive methods of sterilizing milk may be made of the greatest service. The seashore homes for poor children which have been established near the large cities on the Atlantic seaboard have fully justified themselves.

It seems to the editor that the author has insisted more strongly than is necessary on the vital importance of a wet-nurse, in view of the very great advances which have been made within a few years in the preparation of artificial foods for infants. For full details as to these processes, the reader must be referred to modern treatises on the diseases of children.

The drugs most worthy of confidence are, in the opinion of the editor, opium and bismuth; in mild cases the former is often not required; the dose varies greatly with circumstances; the latter can safely be given in ten-grain doses, every three hours, to a child of six months. Calomel does not now enjoy the reputation in this country that it does in Germany, though it has its advocates here. For more minute details see works on children's diseases.]

#### CHAPTER IV.

##### TYPHLOITIS AND PERITYPHLOITIS.

(*Typhloitis Stercoralis.* Inflammation of the Cæcum.)

**Ætiology and Pathological Anatomy.**—Inflammation of the cæcum and its vicinity has a special place among the diseases of single portions of the intestines. The reason why circumscribed inflammation so often develops here is to be found in the peculiar anatomical arrangement of the cæcum and its appendix, the vermiform process. This arrangement explains why faecal masses or foreign bodies are easily retained in the cæcum, and give rise to an inflammation of it.

Inflammation of the cæcum is due, in most cases, to an accumulation of faeces in it, and hence it is usually termed *typhloitis stercoralis*. Since the causes producing the inflammation are usually permanent in their action, the anatomical inflammatory changes are generally much more intense in perityphloitis than in the other forms of intestinal catarrh. The inflammation attacks the whole intestinal wall, and sometimes even invades the surrounding connective tissue, being then called perityphloitis.

The great majority of severe cases of perityphloitis do not start from the cæcum itself, but from the vermiform appendix. This rudimentary portion of the intestine, so unimportant physiologically, plays a great part in pathology. Small faecal masses from the cæcum often enter the vermiform appendix, and, under some circumstances, may remain there. The fluid in them is absorbed, they are very often incrustated with lime-salts, and thus the little so-called "faecal calculi" are formed. In many cases the return of faecal masses into the cæcum is probably hindered by the valve at the orifice of the vermiform appendix, Gerlach's valve. Foreign bodies, like little seeds of fruit, often enter the vermiform appendix and give rise to the formation of a faecal calculus. These calculi often have

such a rounded shape that they were formerly considered, very erroneously, to be retained cherry-stones.

In many cases faecal calculi may remain in the vermiform appendix for a long time without producing any further injurious results, but as a rule they cause a mechanical irritation of the mucous membrane which leads to inflammation, and often, in some circumscribed spots, to a pressure necrosis, and later to ulceration of the vermiform appendix. If the ulcer does not cicatrize—it always may—the ulceration gradually deepens. When there is, finally, perforation of the vermiform appendix, we have either a circumscribed or a general purulent peritonitis, according as adhesions have or have not formed in the vicinity. Although general peritonitis almost always ends fatally, the circumscribed purulent perityphlysis may, at least in a number of cases, finally recover (*vide infra*).

**Clinical History.**—The symptoms of simple typhlysis stercoralis sometimes develop quite rapidly, but in other cases they are preceded by somewhat protracted prodromata. The latter are chiefly constipation, which may at times be interrupted by diarrhoea, and occasional dull pain in the ileo-caecal region. These symptoms gradually or suddenly increase. The pain in the ileo-caecal region, in particular, becomes more intense, and prevents the patient from making any considerable movement. Sometimes there is complete stoppage, but in other cases small amounts of faeces are still passed. The patient frequently vomits one or more times. The general health is also much disturbed. The patient, as a rule, is dull, has no appetite, and has a moderately high fever, somewhere between 101° and 104° (38.5°–39.8° C.), the course of which has nothing characteristic.

The most important signs for diagnosis come from the physical examination of the abdomen. The abdomen as a whole is often moderately swollen by meteorism. The collection of gas probably takes place chiefly in the ileum, above the part of the intestine which is narrowed by the accumulation of faeces. The meteorism often is entirely absent or is only slight, and then we may notice by mere inspection a marked prominence in the region of the caecum. If we examine more closely we perhaps meet with very considerable sensitiveness and tenderness on pressure in the same region. We also feel a resistance, which is either diffuse or well-defined, exactly like a tumor, and which gives flatness or a dull tympanitic resonance on percussion. This characteristic ileo-caecal tumor, which usually confirms the diagnosis, is caused in part by the collection of masses of faeces, which often seem quite compressible, and permit us to determine approximately the portion of intestine affected, and in part by the materially thickened intestinal walls, and eventually by the inflammatory exudation in the vicinity. In their clinical relations there is no sharp distinction between typhlysis and perityphlysis, and inflammatory processes which rise from the vermiform appendix. The further course only can make the distinction possible.

Most cases of simple typhlysis stercoralis take a favorable course. If the patient has timely care and proper treatment the pain and fever gradually disappear. Large dejections follow, and after ten days to three weeks complete convalescence sets in. The abnormal resistance in the region of the caecum due to the thickened intestinal walls may often be felt, of course, for a much longer time. A tendency to constipation is also apt to be present for a long time. Relapses are not uncommon, and it not infrequently happens that people who have once had typhlysis may be again attacked later on by the same affection.

Typhlysis takes a more severe course in the happily quite rare cases where the intestinal stenosis as a result of retention of faeces is well marked. The meteorism is greater, the vomiting is more frequent, and finally assumes a decidedly stercoraceous character. The constitutional symptoms are much more severe. The patient is extremely dull, the skin is cool and livid, the pulse is small and

frequent. In such cases death may ensue with all the signs of general collapse, if we do not finally succeed in causing the evacuation of feces and hence removing the obstruction.

The symptoms of perityphlitis are essentially the same as those of typhlitis, but they are usually of a higher degree of severity. The resistance to be felt in the region of the caecum is less sharply circumscribed and is deeper seated. As a rule there is less meteorism where perityphlitis predominates than in typhlitis. The pain is usually very severe, and often shoots into the right leg, where there may be numbness and formication; but, on the other hand, there are cases in which quite extensive perityphlitic processes cause very slight subjective symptoms for a long time.

[It is to be remembered that the relation of the appendix to the caecum is not a constant one, and that the seat of the tumor is therefore not precisely the same in all cases. The induration or resistance may extend well up toward the liver or backward into the flank. Especially in those cases in which the appendix lies backward near or over the brim of the pelvis, the tumor may be distinctly felt in the rectum or vagina, the digital exploration of which should never be neglected in cases attended with any uncertainty.]

The course of perityphlitis is always tedious, but in favorable cases we may see complete absorption of the inflammatory products and recovery. Severe cases often end by forming abscesses, which may be ichorous. The local symptoms do not disappear, the fever continues and assumes a septic character. Finally, if the abscess tends to break externally, the swelling in the ileo-caecal region becomes more prominent and more sharply defined, the skin becomes thin and red, there is fluctuation, and the abscess breaks spontaneously, if it has not been opened previously. Besides perforation outward, we also meet with perforation into the abdominal cavity, with a consecutive general peritonitis, and sometimes perforation into the ascending colon, with evacuation of pus into the bowels and final recovery. [Occasionally the pus is discharged into the bladder.]

An unfavorable complication repeatedly observed in perityphlitis is an extension of the inflammation to the ileo-caecal vein, which results in a purulent phlebitis of this and also of the portal vein. A general pyæmic condition develops, with chills and marked elevation of temperature. This almost always ends fatally, and at the autopsy we usually find many metastatic abscesses in the liver.

The **diagnosis** of typhlitis and perityphlitis may easily be made in most cases from the peculiar localization of the swelling and tenderness, and by paying attention to the general course of the disease. During life we can merely conjecture whether the special origin of the inflammation is in the caecum or in the vermiform appendix, but we can never determine this with certainty, since in both cases the type of the disease, as we have said, is almost precisely the same. The further course of the disease is the only means of deciding whether the inflammation has remained circumscribed, or has invaded the adjacent parts in the manner mentioned above.

Chronic cases may be confused with new growths, especially with cancer, arising from the caecum or the vermiform appendix. Tumors of the right kidney, or the right ovary, and also psoas abscess, after caries of the vertebrae, have in some cases given rise to false diagnoses. In such doubtful cases we are usually able to form a definite opinion only after long and careful observation.

We may mention here in addition that in rare cases there may be a closure in some part of the vermiform appendix. The portion behind this closure is then gradually more and more distended by the secretion of the mucous membrane, and thus the so-called dropsy of the vermiform appendix is developed, which may give rise to a tumor which can be felt in the ileo-caecal region.

[In brief the early signs and symptoms are those of a local peritonitis, the seat of which is generally highly suggestive of its origin in the appendix. In some cases the symptoms are not indicative of serious trouble, and patients not infrequently walk into the outpatient departments of hospitals for advice. It is unnecessary to say that such should be put at absolute rest in bed with the utmost promptitude.

In women the diagnosis is somewhat complicated by the possibility of acute inflammation about the uterus or its appendages. In both sexes the possibility of the serious error of mistaking appendicitis for typhoid fever is to be constantly borne in mind. Acute intestinal obstruction affords another, though practically less serious, possibility of error.

The tumor may require two or three days for its development.]

The **prognosis** in every case of typhlitis and perityphlitis is to be given with some reserve, since we can not foresee the further course of the disease. A favorable termination, however, is by far the most frequent, and the rule is that the cases are mild and the inflammation is confined to the cæcum. In severe cases of perityphlitis, which end in suppuration, all depends upon whether a general peritonitis ensues or not, and then, if the inflammation be limited, whether the patient's strength is sufficient or not to sustain him until the abscess finally heals. If his strength holds out, he may sometimes recover after the disease has lasted for months.

The **treatment** of typhlitis has two tasks to accomplish: first, to remove the accumulation of feces, which in most cases has caused and which still keeps up the inflammation, and, in the second place, to prevent, if possible, the further extension of the inflammation, when it has once appeared. Unfortunately, the accomplishment of these two tasks are opposed to each other, and thus, in a given case, it is often hard to decide whether to satisfy the first indication by prescribing cathartics, or the second by prescribing opium. In general, as we believe, the fear of the harm which cathartics may do by tearing any adhesions formed, etc., need not be carried too far. In fresh cases of simple typhlitis stercoralis, which come on with manifest stoppage and a palpable fecal tumor in the region of the cæcum, we may always prescribe cathartics like castor-oil or rhubarb, if only we exercise due caution about it. When there are copious dejections after a few spoonfuls of castor-oil, the pain and fever usually speedily disappear. If we do not wish to be imprudent in cases where marked tenderness leads us to suspect that the peritoneum is already involved, we may order large enemata of water instead of cathartics, and these often act well. In cases, too, where there are signs of intestinal stenosis, we may hope for the best results from large enemata repeated three or four times a day.

If the inflammation has extended to the parts adjacent to the cæcum, and if, accordingly, we have a perityphlitis, cathartics are no longer proper, and are even sometimes injurious. The treatment then is chiefly to give opium, half a grain to a grain (grm. 0.03-0.06) of the extract every hour or two, according to the severity of the case. By prescribing opium we soonest attain a cessation of the pain and a limitation of the inflammation. If we suspect a large accumulation of feces besides the perityphlitis, or if symptoms of intestinal stenosis appear, the opium treatment can be combined very well with large enemata.

The local treatment of typhlitis and perityphlitis is often of great service. In most cases an ice-bag on the ileo-cæcal region is well borne and relieves the pain. If there is very much tenderness, we can employ local blood-letting, eight to fifteen leeches, in robust persons, with very good results.

If the signs of a local abscess-formation appear, we may replace the ice-bags by warm compresses or poultices. We do not take the useless trouble of reducing

the fever by quinine, but we try to keep up the patient's strength as much as possible. If there is fluctuation externally, we should open the abscess and treat it antiseptically. We must refer to the text-books on surgery for all the details.

[Tait and his followers deprecate the use of opium in peritonitis of this as well as of other forms, and advocate saline laxatives as a means of reducing congestion. The profession at large, however, in this country and in England, do not adopt his views. Absolute rest in bed is to be secured as early as possible, and an exclusively liquid diet is to be enforced, the nourishment being given in such quantities and at such intervals as the condition of the stomach and other features of the case seem to indicate; but four to six ounces every two hours should rarely be exceeded. It should be remembered that grave cases of this affection are of short duration, and that death from simple exhaustion is not to be dreaded. The editor has of late followed a plan of treatment suggested to him by Dr. Sabine, of Brookline, Mass., whose experience with it has been fairly large. No food whatever is given until the temperature is normal, even if this period extend to a fortnight. Water is freely allowed, and small quantities of stimulants may be administered if desirable. Morphine is given in small doses, not exceeding one eighth of a grain, if there is pain or restlessness, however slight. Peristalsis is thus discouraged, the metamorphosis of tissue is delayed, bodily and mental rest are secured. No attempt is made to move the bowels. The favorite local application with us is a hot poultice.

In fulminant cases, with perforation and general peritonitis at the start, the results of surgical and medical treatment are alike bad. In the ordinary run of cases the peritonitis is at first local, though it may at any time become general from rupture of the limiting adhesions, and herein lies one of the main dangers and arises the necessity of the greatest watchfulness. Abscess formation probably does not occur unless perforation takes place; but we have at present no certain criterion, at least during the first three or four days, by which we can determine the existence of perforation. Hence springs the doubt as to whether to operate, and how soon. If the tumor consists only of feces and simple inflammatory exudation, it will be passed along and absorbed unless perforation takes place. If an abscess has formed, spontaneous cure is highly improbable unless the pus be discharged into the intestine, bladder, or vagina—avenues which are far less desirable than that afforded by an external incision. Fitz advocates waiting for three or four days at least, and then being guided by the development of the general and local symptoms as to whether to operate or not. It may be stated as a general rule that in cases where the existence of perforation is doubtful, but the symptoms as a whole are grave and increasing, it is wiser not to postpone incision, the consequences of an unnecessary but properly performed operation being less serious than those of overmuch delay.

In mild cases, and those in which delay is decided on, opium in some form should be given in sufficient amount to relieve pain and allay restlessness; but anything like narcotism is to be avoided, lest the effects of the opium lead the attendant into a feeling of false security. In recurrent cases it is probably wiser to excise the appendix between attacks, unless the patient is so situated that he can put himself under skilled treatment on the first threatenings of an attack. The necessity of so doing should be carefully explained to him. As to methods of operation, the reader is referred to works on surgery.]

## CHAPTER V.

## PERFORATING ULCER OF THE DUODENUM.

THERE is a form of ulcer of the duodenum, especially of its upper, horizontal portion, which is precisely analogous to the round gastric ulcer in regard to aetiology, pathological anatomy, and, very largely, symptomatology. The ulcer is probably also due in most cases to the action of the acid gastric juice on the duodenal mucous membrane, under conditions which have been mentioned more fully in the aetiology of gastric ulcer. We must mention here the noteworthy fact that, after extensive burns of the external skin, ulceration of the duodenum, rarely of the stomach also, has been repeatedly observed. This is probably due to the plugging of a duodenal vessel by an embolus from decomposed masses of blood.

Ulcer of the duodenum is much rarer than the round gastric ulcer, and, in distinction from the latter, it has been found decidedly oftener in men than in women.

Many cases of ulcer of the duodenum run their course entirely without symptoms, or they cause symptoms when sudden hæmorrhage appears, from erosion of the pancreatico-duodenalis, gastro-duodenalis, etc., with hæmatemesis and bloody stools, or the sudden signs of peritonitis from perforation. In many cases a type of disease exists for a long time whose symptoms, as we have said, are so like the clinical symptoms of gastric ulcer that we can very rarely distinguish the two forms with certainty during life. We notice especially continuous or neuralgic pain, which, in ulcer of the duodenum, has its chief seat in the right hypochondrium. Severe gastric symptoms, especially vomiting, are not as common as in gastric ulcer. The general health and general nutrition may remain quite undisturbed for a long time.

Ulcer of the duodenum ends by cicatrization and recovery, or by cicatrization and the formation of stenosis, with secondary dilatation of the upper portion of the duodenum and of the stomach. In regard to the different adhesions and perforations of the ulcer into neighboring organs, we may refer to what has been said of gastric ulcer.

The treatment must be governed by the same principles which were laid down in the treatment of gastric ulcer, especially as the diagnosis is usually doubtful.

## CHAPTER VI.

## TUBERCULOSIS OF THE INTESTINES.

TUBERCULOSIS of the intestines is in most cases a secondary disease, and is one symptom of a more extensive general tuberculosis. It develops most frequently in the course of chronic pulmonary tuberculosis, and depends here, as we have seen, upon an infection of the intestines by the tubercular sputum that has been swallowed.

Intestinal tuberculosis, however, may also be a primary disease, and the source of further extension of tuberculosis over the body. "Tuberculosis of the abdominal organs," which usually comes from the intestines, has a clinical significance, especially in children. It is not improbable that in such cases the first infection of the intestine comes from without, and that the tubercular poison is taken into the body with the food. Here we must suspect especially the milk from cows with pearly distemper—that is, with tubercular disease.

The anatomical changes in intestinal tuberculosis are precisely analogous to the

tubercular changes in other mucous membranes. The tubercular new growth has its origin usually in the lymph-apparatus of the intestine, in the solitary follicles, and in Peyer's patches. The first miliary tubercles form beneath the epithelium, and soon fuse with one another into a diffuse infiltration. In its further course the infiltration on one side extends deeper into the surrounding tissue, so that it attacks the submucous and muscular coats even to the serous coat, and on the other side, by the destruction of the new growth which begins at the surface and constantly spreads, tubercular ulcers are formed. We can often make out with the naked eye single miliary tubercles or groups of them at the base or in the infiltrated edges of the ulcer. This is especially plain in deep-seated ulcers on the corresponding portion of the serous coat. The form of the larger tubercular ulcers is often irregular. In many cases the long diameter of the ulcer is parallel to the circumference of the intestine, so that the girdle-like ulcers, which are especially characteristic of tuberculosis, are formed.

Tubercular ulcers are situated both in the large and in the small intestines. They are usually most marked in the vicinity of the ileo-caecal valve. Tubercular ulcers in the stomach are extremely rare. Besides the intestinal tuberculosis there is very often tuberculosis of the mesenteric lymph-glands, and also frequently tuberculosis of the peritoneum.

The symptoms of intestinal tuberculosis are usually quite subordinate to the symptoms caused by other co-existing tubercular affections. There may often be quite extensive tubercular ulcers without any marked symptoms, but, as a rule, the onset of diarrhoea turns the attention to the intestinal complication (see the chapter on pulmonary tuberculosis).

Primary tuberculosis of the abdominal organs sometimes presents quite a characteristic type of disease, especially in children. This was termed by the older physicians *tubes mesenterica*. The chief feature of this type of disease consists in a progressive general emaciation and anaemia, which is usually associated with a persistent hectic fever, which obstinately resists all the remedies employed. The abdomen is usually swollen by meteorism, but it is sometimes flat or sunken. In some cases, but less frequently than was formerly believed, we can feel the swollen mesenteric lymph-glands through the abdominal wall during life. The liver may be enlarged and its lower border can often be felt. The bowels are irregular, and there is usually a moderate diarrhoea, persisting in spite of all remedies. The invariably fatal termination is due to an increase of the general marasmus, or to a final acute tubercular affection, like miliary tuberculosis or tubercular meningitis. The autopsy shows tuberculosis of the intestines, peritoneum, lymph-glands, liver, etc., to a greater or less extent. The lungs may be quite free from tuberculosis. We will return to this affection in the description of tuberculosis of the peritoneum.

The treatment of intestinal tuberculosis can be only symptomatic. Besides the general dietetic treatment which seeks to keep up the patient's strength as far as possible, medical interference is demanded by the abdominal pain and diarrhoea. The chief remedy is opium, which, alone or in combination with tannin, acetate of lead, etc., acts most rapidly in relieving the intestinal symptoms. Warm poultices and wet compresses give the best service for local applications.

In other respects the treatment coincides with the general treatment of tuberculosis (*vide supra*).

---

## CHAPTER VII.

## SYPHILIS OF THE RECTUM.

IN not very rare cases we see in the rectum, especially in its lower portions, extensive syphilitic ulcerations, which produce a severe and practically important type of disease. The more intimate relation between syphilis of the rectum and the general syphilitic process is not perfectly clear. According to quite a widespread opinion, the infection of the rectum comes from the secretion trickling down from the ulcers of the genitals. The facts seem to support this view, since syphilis of the rectum is seen much more frequently in women than in men. Some authors have even asserted that all the so-called "syphilitic" ulcers in the rectum have no connection at all with genuine syphilis, but are chaneroids. It is in fact striking, even if it by no means proves such a hypothesis, that, at the autopsy of people who have died of "syphilis of the rectum," we rarely find definite syphilitic changes in other internal organs—a fact which we also can confirm.

The most characteristic mark of syphilitic ulcers in the rectum is their tendency to form cicatrices and stenoses. This result of the ulcer is also important in its clinical relations, since the chief symptoms of the disease usually begin with the development of the stenosis. The seat of the stenosis is usually so low down that we can conveniently reach it with the finger, on a digital examination of the rectum during the patient's life. The rectum narrows like a funnel upward, and we can feel the quite sharp edge of the ring-like cicatrix with the point of the finger. This funnel-shaped stenosis of the rectum is so characteristic of syphilis of that organ that, in almost all cases, we can make the diagnosis with perfect certainty from this alone.

The rectum and the descending colon are usually dilated above the stenosis, and here extensive, irregular ulcerations, with undermined edges, are usually found in the mucous membrane. These are partly of a specific nature, and partly diphtheritic ulcers caused by the pressure of the accumulated fecal masses.

The symptoms of syphilis of the rectum usually develop quite gradually. At first the bowels are irregular, and there are disturbances of defecation which stubbornly resist the ordinary remedies employed. There are sometimes, in the first stage of the disease, frequent and severe hæmorrhages with the dejections, as we have seen, and for a long time these may falsely be considered to be "bleeding from hæmorrhoids." The symptoms become more marked as cicatrization of the ulcer increases and as stenosis of the rectum develops. There is usually a decided catarrh of the rectum, so that the thin stools contain a large admixture of mucus and pus. The patient's condition is extremely distressing, from the pains with the frequent but always scanty dejections, and from the severe tenesmus. Nodular thickenings and prolapse of the mucous membrane, and sometimes true hæmorrhoids, form about the anus. The patient's strength constantly diminishes from the pain and the continual diarrhœa. He finally becomes emaciated, looks very pale and wretched, and has fever toward night. Death ensues from increasing general weakness, or rarely from a terminal peritonitis due to perforation, after the whole disease has lasted one and a half to two and a half years.

This unfavorable termination unfortunately seems to be the rule in all the cases described; hence the prognosis is to be regarded as very serious in all cases of syphilis of the rectum. Improvement worthy of mention, or even perhaps recovery, is possible only when the disease is recognized at the outset and properly treated.

At the outset of the disease the treatment, of course, must consist chiefly in an

energetic general attack upon the syphilis by mercurial inunction and iodide of potassium; but, as soon as the characteristic funnel-shaped stenosis of the rectum has formed, we can not expect much from anti-syphilitic medication, since this can no longer exert any influence on the cicatrices and their results. Improvement is now to be obtained only by mechanical dilatation of the stenosis by bougies, or, if this is not enough, by a surgical operation. A suitable local treatment by irrigation is also of benefit to the catarrh and to the ulcers that still exist in the rectum. Internally, we may continue to use iodide of potassium.

## CHAPTER VIII.

### CANCER OF THE INTESTINES.

THE development of cancer is far more rare in the intestine than in the stomach. Carcinoma is seen with any frequency only at the lower end of the intestine, in the rectum. In other parts the points of election for the development of carcinoma are the colon, especially at its bends, the cæcum and vermiform appendix, and the small intestine, especially in the region of the papilla duodenalis.

Most cancers of the intestine appear in the form of ring-like swellings that take in the whole circumference of the intestine. More rarely we find a more diffuse papillary proliferation, extending over a larger surface of the intestine. There is often quite an extensive destruction of the new growth on the surface of the cancer, from which deep ulcerations arise. We sometimes find metastases in other organs; for example, the lymph-glands, the abdominal cavity, or the liver. In its histological structure, cancer of the intestine is to be regarded as invariably a cylindrical-celled carcinoma, which sometimes shows a plainly glandular structure—adeno-carcinoma—and sometimes that of the other forms of cancer—scirrhus, medullary, or colloid.

Cancer of the intestines, like all cancers, occurs chiefly, if not invariably, in advanced life.

The clinical symptoms of cancer of the intestines are only in a part of the cases so pronounced that we can make a sure diagnosis of the disease. Cancer of the rectum, however, presents a characteristic picture.

Cancer of the rectum begins usually with distress at stool and pain in the rectum, which at first comes only with defecation, but later becomes almost continuous. The pains often shoot into the neighboring parts—the thighs, the genitals, etc. The local symptoms gradually increase, the stools often contain some mucus and blood, and diarrhoea alternates with obstinate constipation. The patient also becomes emaciated, and constantly grows weaker and more miserable. Finally, we often find a complete paralysis of the sphincter ani, so that a mucous, bloody fluid constantly comes from the half-open anus. The diagnosis can almost always be easily and surely made by digital examination of the rectum. We feel the firm, nodulated proliferations of cancer, and we can usually make out with approximate accuracy its extent and its invasion of neighboring organs, like the vagina and bladder. Examination with the rectal speculum makes the diagnosis more accurate. In some cases the destruction of the new growth may cause perforation into the organs mentioned, and we can easily understand the results of this, such as cystitis, purulent discharges from the vagina, etc. We may also have peritonitis from perforation. Secondary cancer

appears with especial frequency in the liver, also in the peritoneum and elsewhere.

Carcinoma of the colon causes, as a rule, only very indefinite symptoms, which for a long time are hard to interpret. These symptoms consist chiefly of distress at stool, obstinate constipation, dull pains in the abdomen, and the signs of slowly increasing general weakness and emaciation. In many cases the stools consist of peculiar, flat, compressed little lumps, which have a certain resemblance to sheep's dung. A similar appearance may also be seen in cancer of the small intestines. In many cases examination of the abdomen gives a negative result, but we can sometimes feel the new growth as an evident tumor through the abdominal wall. In such cases, however, it is almost always difficult to decide upon the seat of the tumor with certainty. It may be very easy to confuse this form with cancers arising from the stomach, the omentum, the mesenteric lymph-glands, etc. We may also be deceived as to the location of the tumor by the fact that sometimes the tumor which is felt in intestinal cancer is not the new growth itself, but corresponds to the fecal masses collected above it. Carcinoma of the cæcum can often not be distinguished for a long time from the tumors caused by chronic typhlitis and perityphlitis. The patient's age, the tedious course and increasing severity of the disease, and sometimes the swelling of the inguinal glands, are the only things that make us think of a cancer. In a case seen at the surgical clinique in Leipsic, a cancer arising from the vermiform appendix ruptured externally through the skin. The rare instances of cancer of the small intestines cause still greater difficulties in diagnosis. In cases where the tumor can be felt externally we can sometimes make out a marked mobility of the swelling, corresponding to the different positions of the affected loop of intestine. Cancer of the duodenum in many of its relations resembles cancer of the stomach, especially of the pylorus. It also leads finally to dilatation of the stomach with its well-known results, as well as to dilatation of the part of the duodenum above the new growth. Cancers situated in the region of the papilla duodenalis usually cause intense and protracted jaundice.

The prognosis of all intestinal carcinomata is absolutely unfavorable. The disease may sometimes last quite a long time, some two or three years, but in some cases the duration of the special symptoms is brief, a few months or even weeks, apparently because the tumor has previously existed for a long time without symptoms. Intestinal cancer terminates with the signs of increasing loss of strength, or it perforates, causing a terminal purulent peritonitis. Extensive ichorous processes in the surrounding connective tissue, phlebitis, and pyæmia, may follow intestinal cancer. A number of cases die with the signs of a slowly or rapidly developing intestinal stenosis (*vide infra*), but in some cases, upon ulceration of the cancer, the already pronounced symptoms of stenosis may disappear for a time.

The treatment must be confined to relieving the patient's symptoms as far as possible. We must provide for easy dejections by a suitable diet and cathartics. Pain, if it is present, must be lessened by narcotics. Surgical treatment of intestinal cancer has shown good results as yet only in cancer of the rectum. The palliation which lasts for a long time after scraping out the rectum is often quite marked, even in advanced cases. In early cases, permanent relief may be given by extirpation of the rectum. If the cancer has advanced too far for this, scraping out the rectum with a sharp spoon may lessen the discomfort at least for a time. All the details are to be found in the text-books on surgery.

## CHAPTER IX.

## HÆMORRHOIDS.

By the name "hæmorrhoids" we mean diffuse or varicose dilatations of the hæmorrhoidal veins, especially of the venous plexuses at the lower end of the rectum. Hæmorrhoids are single large varices, which usually rise from the sub-mucous layer, and push the mucous membrane out before them. If they are situated outside of the sphincter and we speak of external hæmorrhoids, in distinction from internal hæmorrhoids, which lie above the sphincter. The size of the nodules varies with the fullness of the dilated veins; but hæmorrhoids, as a rule, do not consist exclusively of dilated vessels, for we often find, at the same time, quite a considerable thickening of the surrounding connective tissue, so that the whole mucous membrane has a swollen appearance, with a polypoid proliferation in parts. The hæmorrhoids usually present themselves as bluish tumors, from the size of a pea to that of a walnut, which surround the anus like a garland. Many of them have a broad base, while others are pedunculated.

The cause of hæmorrhoids is, chiefly, frequently-repeated stasis in the veins affected. The hindrance to the venous blood return has sometimes a purely local cause. Thus hæmorrhoids quite frequently develop in persons with habitual constipation, and hence in those who lead a sedentary life. Hæmorrhoids also occur as a result of stasis in the portal system, in cirrhosis of the liver, etc., and finally in general disturbance of the circulation, as in diseases of the heart and lungs. Quite often, however, we can discover no sufficient cause for the development of the disease, and we are then forced to the hypothesis of a local disease of the affected venous plexus, which is probably often connected with an individual, and apparently sometimes hereditary, predisposition. We most frequently see hæmorrhoids in men in middle life.

Hæmorrhoids sometimes cause only slight symptoms, or none at all, but in other cases they are a tedious, burdensome, and even distressing evil. The chief symptom is pain, which is felt as a constant burning at the anus, but which increases to great severity at each defecation. There is much pain when the hæmorrhoids and the surrounding tissue gradually get into an inflamed condition. In the skin about the anus, erythema, excoriations, and sometimes little but very painful fissures are formed. The mucous membrane at the lower end of the rectum is often found in a catarrhal state, which gives rise to the presence of pus and mucus in the dejections—"mucous hæmorrhoids." Sometimes there is a genuine phlebitis in individual hæmorrhoids, which ends by forming an abscess. There is very severe pain if an internal hæmorrhoid is pushed out by the strain and pressure at stool and is strangulated by the sphincter. Since all the conditions mentioned—marked temporary filling, inflammation, and strangulation of a hæmorrhoid—must at times give rise to a great increase of the disturbance, we can understand why we often hear such troubles spoken of as "attacks of hæmorrhoids."

Hæmorrhoidal bleeding is a frequent and familiar symptom, which rises from a rupture of the dilated veins, and usually comes on at stool. The hæmorrhage is seldom very large, so that the loss of blood is in itself very rarely dangerous. The swelling of the varices after the hæmorrhages have ceased explains why the hæmorrhoidal symptoms are apt to be less marked as long as there are hæmorrhages than when there are none. Hence the old term of the "golden vein" for hæmorrhoidal bleeding.

Besides the local symptoms mentioned, in the anus, there are sometimes other symptoms which are due to an implication of the neighboring venous plexuses,

the vesical, prostatic, and sacral plexuses. There is often pain in the sacral region, difficulty in micturition, and sometimes even blood in the urine—"vesical hæmorrhoids"—and in women vaginal catarrh, anomalies of menstruation, etc. Since the symptoms of some primary disease in the liver, or heart, or of other co-existing morbid conditions, like abnormal corpulency, or chronic gastro-intestinal catarrh, may be added to the general picture, we can comprehend why medical superstition has found in hæmorrhoids an excuse for the strangest ideas, like that of "transposed hæmorrhoids"!

The treatment of hæmorrhoids is usually no easy task, since the disease often has causal factors which can not be removed. In all cases where there are large hæmorrhoids causing severe symptoms, there is only one radical cure—removal by operation—which is not dangerous and not hard to perform. It is best done by squeezing the nodule with a clamp and burning it with the thermo-cautery. Details in regard to it may be found in the text-books of surgery.

If single nodules are inflamed, we may apply ice locally, or under some circumstances local blood-letting is to be preferred. If an abscess forms it must be opened. We try to replace strangulated hæmorrhoids carefully and slowly with the oiled finger.

The treatment of chronic hæmorrhoidal symptoms consists chiefly in looking out for regular and easy movements of the bowels, because the local discomfort can thus be best relieved. We must also attend to any underlying trouble, like disease of the liver or heart. The food to be prescribed depends upon the patient's physical condition. It is usually wise to limit the supply of meat, and to recommend instead fruit, vegetables, light farinaceous food, and rice. It is well to prescribe sufficient physical exercise, cool baths, under some circumstances sitz-baths, and rubbing. We must also consider cathartics, especially the bitter waters, the springs at Marienbad and Kissingen, and the regular use of cold enemata, rhu-barb, aloes, etc. Sulphur is a remedy very often used in the treatment of hæmorrhoids, the chief ingredient of most of the "pile powders" for internal use. It may be ordered thus:

R Sulphuris loti,	{	.....ââ 3 ss. (grm. 15);	
Potassii bitartratis,			
Sacchari albi,	{	.....ââ 3 ijss. (grm. 10).	M.
Elæosacchari citri,*			

Hæmorrhoidal bleedings, as has been said, are only exceptionally so severe as to require interference. We may use ice, chloride of iron, or tamponing the rectum.

[Persistent and intelligent treatment will often bring about very great relief, or even complete cure, in chronic cases. There are many local applications, each of which has its warm advocates—so many that it is not possible here to go into details. Suffice it to say that an astringent with or without an anodyne may be used as an enema, in suppository or in ointment. The fluid extract of hamamelis, glycerine, and some other remedies given by the mouth, are reported to have afforded good results.]

---

\* Powdered sugar, ʒj; volatile oil, gtt. ij. M.

## CHAPTER X.

## HABITUAL CONSTIPATION.

A PERSISTENT tendency to constipation is a frequent symptom in many different diseases, where it is almost always due to a diminution of the normal peristaltic movements of the intestines. In many conditions this diminished energy of peristalsis is only one symptom of general weakness of the body. Thus we see in all possible forms of chronic disease, which are associated with loss of flesh and strength, that the intestinal movements become sluggish, and hence the dejections are delayed; yet many other causes have a similar action. The small amount of food taken, and its quality, as it is often composed largely of fluids and "non-irritating" substances, and also the rest in bed, or at least the slight amount of physical exercise taken—all these conditions play a part in the constipation frequently seen in patients with chronic disease.

In other cases we have to do with disease of the intestine itself, as the cause of the habitual constipation. In chronic primary and secondary intestinal catarrh we often observe a persistent tendency to constipation, which is only occasionally interrupted by diarrhoea. Many factors also act here simultaneously. The chronically inflamed membrane, which is often covered with mucus, is less irritable, and hence it is more difficult to excite the intestinal movements by reflex action than if the intestinal mucous membrane is normal. The muscular coat itself often takes part in the morbid changes, and atrophy of it has been repeatedly observed as a result of chronic intestinal catarrh. The habitual constipation in chronic affections of the peritoneum is explained in a similar way, as the muscular coat is also directly affected by collateral cedema, etc. We must mention here the constipation in all forms of chronic jaundice, which depends in part at least upon the absence of the irritation which the bile normally exerts upon the intestinal wall.

We very often see chronic constipation in the different diseases of the nervous system, especially of the brain and spinal cord. Here we have to do with abnormal inhibition or direct disturbance of the nervous stimulus, which is necessary to cause the intestinal movements. Abnormal mental conditions are also of great influence. In many psychoses, especially in hypochondriasis, melancholia, and many forms of hysteria and neurasthenia, we very often see habitual constipation.

While constipation, in the diseases thus far described, is a symptom which is more or less subordinate to the other symptoms of the disease, there is a form of habitual constipation, extremely important practically, where the constipation is the chief or almost the sole symptom, and accordingly it may be regarded to a certain extent as a disease *sui generis*. Patients very often come to the physician who look perfectly well, and are entirely able to attend to their business, but who are constantly troubled because they can not have a movement of the bowels every day, like other people, but only every three or four days, or even less frequently. In some cases of this sort the patient's complaint is limited to the delay in the stools, but more often a number of other abnormal subjective sensations and disturbances are added to the habitual constipation, and these are regarded as a result of the constipation by the patient himself, and are usually observed with great care and excessive accuracy. These are the cases which may lead to the highest degree of hypochondriasis. The patient's whole thought and consciousness are busied almost exclusively with his own morbid condition, through which he has lost all energy and joy in life. He seeks aid from different physicians and from quacks, usually without any real confidence, and without having the perseverance to follow out the directions given. Besides the trouble with the bowels, such patients complain chiefly of dizziness, of pressure, coldness, and other abnormal sensations

in the extremities, very often of cold sweaty hands, of a feeling of oppression in the chest, of disturbed sleep, etc.

It is not always easy to interpret these cases correctly. The nervous affection, like hypochondriasis or neurasthenia, is often the primary disease, which is followed by constipation, while in other cases the habitual constipation leads secondarily to the nervous depression. The two conditions usually form a vicious circle, since each of them is apt to keep up and to increase the other. The cause of primary habitual constipation can not usually be discovered. Probably we often have to do with a congenital weakness of the muscles or of the innervation of the intestines, since many cases date from early youth.

The treatment of habitual constipation is a difficult and often a thankless task, and it demands patience and professional tact. It goes without saying that we must first of all look for the causal factors. If we succeed in improving the underlying disease—as, for instance, the chronic gastro-intestinal catarrh, the chronic affections of the heart or lungs, the anæmic conditions, or certain nervous troubles—a regulation of the bowels often follows of itself. In ordinary habitual constipation we must first attend to the patient's diet. Since most of these patients also suffer from symptoms of nervous dyspepsia, they are usually very careful in their diet, and take only a little, easily digestible, and chiefly liquid food. It is no wonder that no good dejections follow such food. Improvement can be obtained only by eating plenty of food which can mechanically stimulate the intestine. Hence we must try to bring the patient back to ordinary "household fare"—to take, besides plenty of meat, a sufficient amount of bread, vegetables, etc. It is a very good thing to recommend especially certain kinds of bread, like Graham-bread or rye-bread, and also larger amounts of butter, besides fruit, prunes, grapes, dates, figs, almonds, nuts, and honey. The well-known remedy of drinking a glass of cold water in the morning before breakfast is deservedly popular. We should be very guarded in giving special cathartics, since the patient easily gets accustomed to them, and then must take them in larger doses. Of the milder laxatives, the different bitter waters like Friedrichshall, do the best service. We usually prescribe one or two wine-glassfuls. The other cathartics, like tamarinds, rhubarb, aloes, gamboge, or jalap, which may sometimes be used regularly for a long time, are prescribed in various combinations, as pills and powders. We may often have to change our remedies and our doses a number of times until we find the right ones.

In the treatment of habitual constipation associated with hypochondriasis, the first rule is to treat the patient's mental condition. We should not make merry over his trouble, nor should we rudely let him feel that we do not consider his complaints so important as he himself imagines. The patient does not deserve to be scoffed at, since his subjective symptoms are to him of the most urgent nature; but it is extremely important to divert his thoughts from his trouble. As in many other reflex processes, so in defecation, the voluntary attention abnormally directed to it has an inhibitory action. Hence we admonish the patient to think of his trouble as little as possible and to begin his regular activities again, and we try to convince him of the groundlessness of his fears. The cathartics, which most patients have already taken freely without the desired action, are usually of no advantage at all. On the contrary, it is almost always necessary to forbid the patient to use cathartics at all. Except by a proper diet (*vide supra*), we try to regulate the peristalsis by external remedies alone. Methodical massage of the abdomen is most employed for this, and also electrical treatment, faradization of the abdominal walls, and faradization and galvanization transversely through the abdomen. To be sure, a good part of the benefit of these methods depends upon their moral effect upon the patient. We must not omit a proper general treatment: cold sponging, baths, a country resi-

dence, and sufficient physical exercise. Finally, it is often very useful to cause the patient to go to the closet at a fixed hour daily, even if there be no special desire for a stool, and to try to have a movement of the bowels. Thus a sort of training and education of the bowels is achieved, even where the patient at first believes it impossible.

By these means only do we succeed in giving the patient renewed courage, and sometimes finally in attaining recovery even in severe and persistent cases. (Compare the chapters on nervous dyspepsia and on neurasthenia.)

## CHAPTER XI.

### STRICTURE AND OBSTRUCTION OF THE INTESTINES.

**Ætiology and Pathological Anatomy.**—Different pathological processes may lead to stricture or complete obstruction of the intestinal tube in different parts. Since in this affection the purely mechanical effect of the intestinal stenosis is the chief cause of the clinical symptoms, the type of the disease is very similar in all the cases of this class, in spite of the manifold anatomical causes. Hence, after enumerating the individual affections which may lead to stricture of the intestines, we can describe their symptoms in common.

The anatomical causes of stricture or obstruction of the intestines are as follows:

1. *Congenital closure* of the intestines is found at the anus, *atresia ani*, and much less frequently in the colon or small intestines. The form first mentioned is the only one of clinical interest, since it may be relieved, at least in some cases, by operation. All the other forms of congenital closure of the intestines are incompatible with a long duration of life.

2. *Tumors and Cicatricial Strictures.*—Cancer of the intestine is the only tumor that has any clinical significance. We have already described its most important anatomical relations and the possibility of intestinal stenosis as a result of it.

We see cicatricial strictures most frequently in the large intestine after recovery from dysenteric ulcers. The syphilitic stenosis of the rectum, which we have already described, is also of practical importance. Typhoid ulcers very rarely lead to cicatricial stenosis. Strictures as a result of tubercular ulcers of the intestines are also extremely rare. Stenosis of the duodenum after the healing of a duodenal ulcer (*vide supra*) resembles, in its clinical symptoms, stenosis of the pylorus, and not stenosis of the intestines.

3. *Intestinal Obstruction.*—The most frequent form of intestinal obstruction comes from the impaction of feces. From the different conditions which cause enfeeblement of the peristaltic movements, an accumulation of feces (*coprostasis*) may arise, especially in the colon, and gradually increase, and finally lead to the fully developed symptoms of intestinal stenosis. Since in such cases a paralysis of the muscular coat has been supposed to be the first cause of the constipation, the occasional stercoraceous vomiting which finally sets in has been termed "*ileus paralyticus*." We must also mention that, in intestinal stenosis from other anatomical causes, coprostasis is often an important factor in increasing the stenosis.

We see obstruction of the intestines from other causes much less frequently than from impaction of feces. In some cases impacted gall-stones have been found, especially in the lower part of the ileum, almost completely stopping up the lumen of the intestine. Genuine intestinal calculi may exceptionally lead to

obstruction. We must also mention here the very rare cases where a large foreign body has been swallowed and wedged itself into some part of the intestine. Such a thing has been seen, especially in children and among the insane.

4. *Intestinal Constriction*.—Although the mechanism of intestinal constriction in external herniæ lies in the domain of surgery, we must mention here the chief causes of the so-called internal intestinal constriction, internal incarceration, or strangulation. In the abdominal cavity itself pouches and diverticula are found, either as normal or abnormal formations, in which single loops of intestine may be caught and constricted. The duodeno-jejunal hernia—the so-called Treitz's retro-peritoneal hernia—is worthy of special mention, and comes from the entrance of a loop of intestine into the duodeno-jejunal fossa. This hernia may become very large. It is sometimes found by accident in the cadaver, not having caused any symptoms during life, but in rare cases it may be the cause of acute internal constriction. We must also mention the hernia of the omental bursa—where a loop of intestine passes through the foramen of Winslow—the intersigmoid hernia, the subcæcal hernia, etc. Diaphragmatic hernia is of greater practical significance because it is somewhat commoner. By this name we designate both genuine protrusions into the diaphragm, and also the passage of abdominal viscera through congenital or acquired (traumatic) defects in the diaphragm. These herniæ may exist without symptoms, or at least without causing any signs of severe disease, but in some cases they cause obstruction by constricting or twisting a dislocated loop of intestine.

Those cases in which abnormal slits and holes in the omentum or mesentery give rise to internal constriction are to be added to the list of the internal herniæ.

Finally, abnormal fibers, membranes, and false ligaments in the abdominal cavity are a comparatively frequent cause of internal constriction. Such cords and bands are sometimes left as the results of a former peritonitis, and may cause actual constriction or bending of single loops of intestine. One such false ligament, which must be specially mentioned, and which may cause intestinal constriction, is found as a prolongation of Meckel's diverticulum. By this we mean that diverticulum which must be regarded as the remains of the omphalomesenteric duct, still persisting, which has its seat, corresponding to the duct, from half a metre to a metre above the ileo-cæcal valve. A firm cord sometimes arises from the free end of this diverticulum, the obliterated omphalo-mesenteric vein, which adheres to some part of the internal abdominal wall and may cause constriction of the intestine. Adhesion of the free end of the vermiform appendix has been the cause of internal constriction in some cases.

5. *Twists (volvulus) and Knots of the Intestine*.—Twists about the mesenteric axis, and complete constriction of a portion of intestine from this cause, are seen most frequently in the sigmoid flexure, especially if the mesentery of the flexure is unusually narrow congenitally. The spontaneous correction of this abnormal condition is hindered by the weight of the loops of intestine filled with gas and masses of fæces, and by other portions of intestine lying on the place of twisting. Sometimes other portions of intestine wind themselves several times about the pedicle of the twisted loop so as to form a regular knot. Such twistings have been seen especially between the sigmoid flexure and a portion of the ileum. External injury sometimes gives rise to the formation of a knot. In some cases abnormally great peristalsis, severe diarrhœa, precedes the appearance of obstruction. We have ourselves seen a case of volvulus in the upper part of the small intestines, as a result of very severe vomiting caused by a remedy for tape-worm given by a quack!

6. *Invagination of the Intestine (Intussusception)*.—If a portion of intestine is pushed into the lumen of the portion that lies next below, we term the process

invagination. The cause of this is probably to be looked for in a diminution or a complete absence of peristalsis in a circumscribed portion of intestine. If now there are energetic movements in the portion immediately above, they push this into the paralyzed portion. In other cases we may, perhaps, suspect a spasmodic state of the muscular coat. We find invagination of the ileum most frequently in the bodies of atrophic children. In such cases it is an ante-mortem symptom, due to the different periods of cessation of peristalsis in the different parts of the intestines.

Besides this invagination, which has only an anatomical interest, sudden intussusceptions are seen, especially often in children up to ten years of age, for which we can usually discover no certain cause, and which in a short time lead to the severest symptoms of intestinal stenosis. Such intussusceptions, which often involve quite long portions of the intestine, may have their seat in almost any part of the intestine. The invagination of the cæcum and a portion of the lower part of the ileum into the colon (ileo-cæcal invagination) is relatively the most frequent. These intussusceptions may sometimes reach such an extent in children that the invaginated portion of the ileum may finally reach the rectum, and sometimes even project externally. Inflammation and adhesions usually appear in the part invaginated. Gangrene of the internal portion, from the constriction of the afferent vessels, is also common. The necrotic portion may be cast off and passed with the dejections, a process which, in some cases, has led to a spontaneous healing of the intussusception and to a cure of the intestinal obstruction caused by it.

We must mention intestinal polypi as a special cause of intussusception, as they gradually pull that portion of the intestine in which they are situated into the neighboring portion next below by their weight. This has been repeatedly observed.

7. *Compression of the Intestine from without*, by tumors of the uterus, ovarian cysts, pelvic abscesses, omental tumors, etc., has been met with in rare cases as a cause of intestinal stenosis. The symptoms of stricture in such cases develop either very gradually or sometimes rather suddenly.

We must now mention certain pathological changes which may follow every obstruction, from whatever causes it may arise.

The further changes in the intestine deserve the chief attention. Above the constricted point it is usually greatly swollen from gas and the accumulation of faeces. The whole intestinal wall is found in an inflamed condition, which is due in part to mechanical action, and in part to the inflammatory germs which are abundantly developed in the abnormally situated intestinal contents. A severe diphtheritic process often develops in the intestine, with ulceration, above the stenosis. In the inflamed, softened intestinal wall, thin from its abnormal distention, a little tear easily occurs in some spot, or more rarely a genuine perforation following an ulcer. Some of the putrefying contents of the intestine thus enter the abdominal cavity, and an intense purulent or ichorous peritonitis is unavoidable. This is why acute peritonitis is so frequent a lesion in persons who die of intestinal obstruction. If the intestinal stenosis has lasted a long time, we usually find in the upper portion of the intestine, besides the signs of inflammation, a manifest hypertrophy of the muscular coat, the result of the abnormally active peristalsis by which the muscle has tried to overcome the obstacle. The intestine below the constriction, in contrast to the part just described, appears narrow, contracted, and empty.

The changes in the other organs correspond to the general inanition. The frequent development of inhalation-pneumonia is easily explained, if severe vomiting has preceded (*vide infra*).

**Clinical History.**—In regard to the clinical symptoms we must distinguish the cases with a rapid, complete obstruction of the intestine from those in which the condition develops gradually, and where there is, therefore, merely a constriction of the intestine, at least for a time.

The first symptom of the partial **intestinal constrictions**, which arise from cicatricial strictures and new growths, from partial blocking up of the lumen, from intussusceptions, etc., is usually a disturbance in defecation. The bowels are costive, they move only at long intervals, and their motion is often associated with pain and tenesmus. In the description of cancer of the intestines we have already mentioned that the faeces passed sometimes have a peculiar, flat, compressed, or scybalous form. Blood and mucus are often mixed with the dejections and are due to the character of the primary disease. In some cases there is no constipation, and there may be even constant diarrhoea. We can easily understand from the physiological conditions that in stenosis of the small intestines, whose contents have an approximately fluid consistency, disturbances of defecation are less apt to take place than in stenosis of the large intestine, where the faecal masses have already assumed a more firm consistency.

Physical examination of the abdomen often gives important and valuable information. The abdomen is usually swollen by meteorism, which arises from the accumulation of gas above the constricted portion. The intensity of the meteorism varies very much in different cases and at different times in the same patient. Meteorism is sometimes absent, especially in stenosis at the beginning of the intestine. There may then be gastrectasis. The marked peristaltic movements, plainly visible through the abdominal walls, are very characteristic of most intestinal constrictions. The contour of single loops of intestine is often marked, at times quite sharply, and then we can sometimes feel the thickened intestinal walls through the lax abdominal wall. We may often decide upon the seat of the stenosis from the location and course of the visible peristaltic movements. In general, it is true that peristalsis is much more noticeable when the stenosis is in the small intestine than when it is in the colon. We must finally state that we have been repeatedly struck by the great extent and strength with which we could feel the pulsation of the aorta through the swollen loops of intestine. If we put our ear to the anterior abdominal wall we can often hear many gurgling and splashing noises, which sometimes have a distinct metallic quality. Eructations are frequent, and in some cases there is occasional vomiting.

The duration of all these symptoms differs with the form of the primary disease. Either gradually or sometimes quite suddenly the symptoms of intestinal constriction pass into those of obstruction. Then the same type of disease develops as is seen in all acute internal strangulations.

The symptoms of **intestinal obstruction** form one of the severest and most frightful conditions known to pathology. The patient's general condition in a short time undergoes a threatening change for the worse. The signs of collapse rapidly develop; the face sinks in and assumes a wasted and sharp expression, the extremities become cool and livid, the pulse is frequent and can scarcely be felt, the voice is weak and obscure. The temperature usually falls, but it occasionally rises. The abdomen is much swollen from meteorism, and is usually very tender on pressure from beginning peritonitis. The passage of faeces and the escape of flatus cease entirely. We often see the peristaltic motions of the intestines above the obstruction through the abdominal walls, but in some cases the muscular coat is so parietic that it is no longer capable of marked peristalsis.

The most characteristic symptom of intestinal obstruction is the vomiting of feculent-smelling masses, the so-called stercoraceous vomiting (*ileus, miserere*). There is often frequent eructation at the beginning of the attack, which alternates with real vomiting. The vomitus at first is of the usual character, but it soon acquires a manifestly putrid, faecal odor. The old opinion is false that in this vomiting real faecal masses were forced backward from the large intestine into the stomach by an antiperistaltic action of the intestine. Stercoraceous

vomiting occurs, not only when the obstruction is in the large intestine, but also in obstruction of the small intestines. In this case we have to do with a putrid decomposition of the contents of the intestine stagnating above the obstruction. Part of this putrid mass reaches the stomach during vomiting, since the pylorus gradually yields to the increasing swelling of the small intestines. The vomiting itself is probably caused in large part by the pulling on the peritoneum, and perhaps by the irritation of the abnormal matter which has entered the stomach.

We must mention, finally, certain facts observed in the different forms of intestinal stenosis, which are of theoretical interest and also of diagnostic importance. In the contents of the intestine stagnating above the stenosis, large amounts of indol and phenol are formed, chiefly from the decomposition of the albuminous substances, and also from the other products of putrefaction. These are in part absorbed and excreted with the urine. Hence, in stenosis of the small intestines we often find that the urine contains an increased amount of indican\* (Jaffé) and phenol (Brieger), but in stenosis of the large intestine the amount of indican in the urine is not increased, because the albuminous substances capable of decomposition are no longer present in the contents of the large intestine to cause it.

The course of intestinal obstruction differs according to the anatomical causes which exist in different cases. In many cases of acute internal strangulation the severe type of general disease above described develops in a very short time, and may lead to death in a day or two, but usually the course is somewhat longer and lasts a week. In intestinal obstruction which develops gradually from intestinal constriction, the disease may go on longer and show many variations in its intensity. In mere intestinal constriction we can make fewer definite statements as to the duration and course of the affection, since the symptoms of the disease depend entirely upon the form of the primary disorder.

In a great majority of cases intestinal obstruction terminates unfavorably. Death results either from increasing collapse or from secondary peritonitis (*vide supra*), or in rare cases from further complications, like pyæmic conditions or pneumonia. Recovery may occur even after the severest symptoms, but it is very rare. The obstructions from impactions are most hopeful for recovery. Impacted gall-stones, fecal accumulations, etc., may be evacuated, after which the severe symptoms disappear. The possibility of recovery in intussusception, by throwing off the gangrenous internal portion of intestine, has been mentioned above. We can not wholly deny that internal strangulations are capable of restoration, although the prognosis must almost always remain doubtful on account of the uncertainty of the diagnosis in any individual case.

In the partial intestinal constrictions, too, the nature of the trouble causes an unfavorable termination in most cases, either from the primary disease itself or from the complete obstruction that finally follows, but the possibility of recovery can not be wholly excluded in certain conditions, like impaction or external compression.

To go into details as to the clinical symptoms of the separate forms of intestinal constriction and obstruction would lead merely to repetitions. In most of the acute and many chronic cases the diagnosis can generally be made only as to the presence of a mechanical obstacle in the intestine, but the nature of the obstruction can at best be merely surmised. Individual factors in reference to this, and in regard to the question of the seat of the stenosis, are contained in the account given above of the aetiology and symptomatology.

---

\* The indican test is performed in the following way: We mix equal volumes of urine and official hydrochloric acid (P. G.), and then add, drop by drop, a concentrated solution of chloride of lime, shaking it after each drop. If now chloroform is added, upon shaking again, the chloroform will take on a striking blue color, if the urine contains any considerable amount of indican.

[The diagnosis of the nature of an intestinal obstruction is so difficult in many cases, and yet so important with reference to treatment, that the editor ventures to introduce tables of differential diagnosis of the more common forms of the condition. These tables are based upon the masterly prize-essay of Treves, of London.

ACUTE INTESTINAL OBSTRUCTION.

CHIEF COMMON SYMPTOMS.—Sudden pain, intermittent or constant, with exacerbations; tends to become constant with time. Vomiting, early, severe, becoming feculent. Constipation, more or less absolute. Abdominal distention. Shock.

	STRANGULATION BY BANDS OR THROUGH APERTURES (25 per cent. of all cases of acute obstruction).	VOLVULUS OF COLON.	ACUTE INTUSSUSCEPTION.
AGE AND SEX	Young adults; rare after 40.	Males as 4 : 1; 40 to 60.	More than 50 per cent. under 10 years.
HISTORY	Previous peritonitis in 68 per cent.; previous attacks of obstruction in 13 per cent.	Previous constipation.	Usually negative.
ONSET	Sudden in 70 per cent.	Sudden.	Sudden in 75 per cent.
PAIN	Early, severe, continuous, with exacerbations.	Early, less severe, intermittent at first, becoming constant with exacerbations.	Early and severe; increasing and later subsiding; at first paroxysmal.
LOCAL TENDERNESS	Absent at first, appears later.	Early over distended coil, and constant.	Common about a tumor.
VOMITING	Early, marked; in 60 per cent. becomes feculent; affords no relief.	Less early, severe, and constant; often affords relief.	Still less early and severe; in 25 per cent. becomes feculent.
CONSTIPATION	Continuous and absolute; no blood.	Early and absolute; no blood.	Absolute rare; diarrhoea not uncommon; blood in 80 per cent.
PROSTRATION	Marked.	Rather less marked; may be dyspnoea.	Marked.
TENESMUS	Absent.	In 15 per cent.	In 55 per cent., and often early.
ABDOMINAL WALL	Flaccid unless peritonitis.	Rigid from early peritonitis.	Flaccid unless peritonitis.
TUMOR	Very rare.	Absent.	In 50 per cent.; invagination sometimes felt in rectum.
METEORISM	Slight, appears about third day.	Early, rapid, increases, and is extreme.	Rare, unless marked constipation.

N. B.—No trustworthy conclusions can be drawn from the seat of the pain as to the seat of the obstruction unless local peritonitis comes on. The pain is usually referred in all forms to the region of the navel. In complete obstruction the pain is constant, though with exacerbations; intermittent pain shows that the obstruction is partial. Coils of intestine are not visible through the abdominal wall in acute cases.

CHRONIC INTESTINAL OBSTRUCTION.

	STRICTURE OF THE SMALL GUT.	STRICTURE OF THE LARGE GUT.	FÆCAL ACCUMULATION.
AGE AND SEX	Adults.	Adults.	Adults; more common in females; the hysterical, lunatics, hypochondriacs.
HISTORY	Cancer, trauma, tuberculosis; disordered, imperfect, irregular action of bowels from time to time, with intervals of comparative ease.	Cancer, trauma, tuberculosis, dysentery; disordered, imperfect, irregular action of bowels from time to time, with intervals of comparative ease.	Previous constipation.
ONSET	Gradual.	Gradual.	Gradual.
PAIN	Intermittent.	Intermittent.	Less prominent.
VOMITING	Late, scanty, feculent only toward end of acute attack; may be provoked by food.	Less prominent, rarely feculent or provoked by food.	Late, scanty, rarely feculent, often absent.
CONSTIPATION	May alternate with diarrhoea; blood points to cancer.	Form of faeces may be altered; blood points to cancer.	Gradually increasing; may be spurious diarrhoea; no blood.
TENESMUS	Absent.	Often present.	Absent.
METEORISM	Not marked, unless acute attack.	Often marked.	Late; generally increases with obstruction.
TUMOR	Only in cancer, and then in 30 per cent.	Only in cancer, and then in 40 per cent.; may be felt in rectum.	Common and distinctive; most easily felt in cæcum; little or no tenderness; sometimes movable, and can be changed in shape.
COILS OF INTESTINE	Marked in proportion to emaciation.	Marked in proportion to emaciation.	Rarely seen.

N. B.—In any form of chronic obstruction, the symptoms of acute occlusion may suddenly supervene.]

We would here make special brief mention of only one frequent form of intestinal obstruction, on account of its practical importance. We mean that form which is caused by the accumulation of large masses of old faeces in the rectum. We sometimes find monstrous accumulations of faeces in the rectum, especially in old women who have previously suffered from habitual constipation, or in whom constipation is due to some other affection. Severe symptoms usually come on quite suddenly, after long-continued mild prodromal symptoms, and these severe symptoms are much like the picture of internal strangulation—severe, sometimes colicky, abdominal pain, great tenderness of the abdomen, which is usually swollen, marked general collapse, loss of strength, a small pulse, an outbreak of cold sweat, vomiting, etc. If we try to give an enema in such cases, very little fluid runs into the rectum. On introducing the finger, it usually strikes solidly on old, hard, faecal masses above the sphincter, and there is often nothing left but to undertake the dirty task of removing at least a part of the scybala with our own hands. We may then succeed, by repeated enemata and by giving cathartics internally, in removing sometimes quite an incredible amount of accumulated faeces, and in obtaining thus a rapid recovery from the condition.

**Treatment.**—As soon as the dangerous signs of intestinal obstruction are recognized by the physician, he must decide in the first place whether the stenosis is not accessible to direct treatment. Hence we first examine in the most careful manner the external points for hernia, that we may not overlook a strangulated hernia. Then we make a digital examination of the rectum in order to decide whether the stenosis may not have its seat here, as from coprostasis, rectal tumors, or perceptible intussusception. Besides that, we of course examine the rest of the abdomen, as far as the patient's condition permits, in order by this, and by any facts in the history, to decide as to the form of the stenosis, from obliteration or compression.

Definite therapeutic measures sometimes follow from the conditions thus indicated. Strangulated external herniae require operative treatment as taught by surgery. We may obtain aid, in some cases of stenosis from impaction, by the prudent use of cathartics. The treatment of faecal impaction is of special importance. We have described the most frequent form of this in detail above. As has already been said, it is usually necessary to remove at least a part of the faeces with the fingers, or some instrument like dressing-forceps or a spoon. In the second place, we may use large enemata of pure water or soap-suds, which must often be repeated four or five times a day, until they have a satisfactory result. These are best given by a funnel and an oesophageal tube ("intestinal tube") introduced as high as possible into the intestine. Cathartics administered internally serve as aids, especially castor-oil and rhubarb.

In stenosis of the rectum from cicatrices and new growths we can also sometimes employ a local surgical treatment, like dilatation or scraping. The treatment of faecal accumulations usually plays an important part here. Finally, the cases of ileo-caecal invagination, in which the lower end of the invaginated ileum reaches the rectum, may yield to local treatment. We may try a partial replacement by a "sponge-sound" (an elastic oesophageal tube to the end of which a sponge is fastened). Blowing in air by the bellows was also recommended for this purpose by the old physicians. As a rule, however, we use here large enemata of warm water, which sometimes seem to exert a favorable mechanical action.

Very often we can not decide with certainty as to the anatomical cause and the seat of the obstruction at the bedside. In these cases nothing but a symptomatic treatment is left for the physician to employ. With constipation we usually try first cathartics, first the weaker, then the stronger, and finally, as a "last resort,"

reguline quicksilver, pure mercury in doses of five to ten ounces (grm. 150-300), which is sometimes claimed to act mechanically in "doubtful cases" by its weight. Except among some defenders of mercury, the present opinion among physicians tends far more to the belief that cathartics are usually of no service, but are often directly injurious by increasing the resistance. Hence we have at present gone over to the treatment of severe internal incarcerations with large doses of opium. Opium acts favorably on the patient's pain, the vomiting is diminished, and, by quieting the peristalsis, the danger of increasing the stenosis and tearing the intestine is also lessened. In fact, the opium treatment has some favorable results on record. Sometimes the first defecation appears during the administration of opium.

Since, therefore, there are many objections against the internal use of cathartics, we may try large enemata in those cases where the seat of the stenosis is not known to be in the large intestine. They must be given with caution, but persistently, and they must often be repeated; then they sometimes give good results, even in severe cases. In numerous instances of fecal vomiting great benefit is also derived from methodical washing of the stomach as recommended by Kussmaul, Cohn, and others. Large amounts of feculent liquid are frequently removed through the tube from the stomach; and indeed it is easy to see that freeing the stomach of its accumulations may favor a more vigorous peristalsis. Even when the nature of the intestinal obstruction precludes definitive recovery, lavage usually gives no inconsiderable relief.

We need not enter into details as to the general treatment. It goes without saying that the patient's strength must be kept up as much as possible, and that in severe states of collapse all possible stimulants must be used, like hot, strong coffee, camphor, and ether. Local applications to the abdomen are usually ill borne on account of the tenderness, still we may try ice poultices or wet compresses. Opium is the best remedy for pain and vomiting, but it must often be replaced by subcutaneous injections of morphine. In cases of extreme gaseous distention the intestinal coils may be punctured with the needle of a subcutaneous syringe and the gas in part evacuated. This sometimes proves very beneficial.

Finally, it must be noted that in severe cases we are justified in proposing laparotomy. Sometimes the existing obstruction may be thus detected and removed. (For particulars, see text-books on surgery.)

[The safety with which laparotomy is now performed has stimulated the study of all affections on which the operation has any bearing. Internal strangulations and invaginations may be relieved, and the portion of intestine containing a non-cancerous stricture can be excised. An early operation offers much better chances, of course. In these days persons should not be allowed to die directly from intestinal occlusion without an attempt being made to restore the permeability of the canal by surgical means.]

---

## CHAPTER XII.

## INTESTINAL PARASITES.

(Helmínthiasis.)

## 1. Tape-worms.

**Natural History of the Tape-worm.**—Three of the tape-worms (*cestodes*) which are found in the intestines have a clinical significance: the *tænia solium*, the *tænia mediocanellata*, and the *bothriocephalus latus*.

1. The *tænia solium* is, when fully developed, two or three metres long. Its head (Figs. 37 and 38) is about the size of that of a pin, and has four projecting cup-like suckers, and in front a beak with about twenty-six hooks. The top of the head is, as a rule, plainly pigmented. A small neck, about an inch long, is

FIG. 37.—(From HELLER.)  
Head of *tænia solium*.

FIG. 38.—(From HELLER.) Head of cysticercus of the brain.

attached to the head, and then follow the single "joints" (*proglottides*) of the tape-worm, of which the youngest, lying near the head, are still very small and short. They gradually increase in length and breadth, and at about a metre from

the head they have an approximately quadrilateral shape. The segments which lie farther down, and which have already reached puberty, have the form of pumpkin seeds, and are nine or ten millimetres long and six or seven wide. The matrix or uterus runs through the middle of each mature segment (see Fig. 39), and from it, on each side, go seven or eight side branches, which ramify like a tree. On one side, a little below the middle, lies the sexual orifice (Fig. 39, *a*). The male sexual organs consist of a number of little clear vesicles in the anterior portion of the segments. The thick-shelled eggs (Fig. 40, 3) develop in the uterus, and contain an embryo with six hooklets.

FIG. 39.—(From HELLER.)  
*Tænia solium*. Mature segment.

The *tænia solium* inhabits the small intestines of man. Its head clings to the mucous membrane so tightly, usually at some point in the upper third of the small intestine, that the neck is often torn off in trying to loosen the worm from the intestinal wall. The rest of the worm, which is in part in many coils, extends to the lower part of the ileum, but only exceptionally into the cæcum. From the lower end long chains, or single mature segments, are often detached, mix with the contents of the

intestine, and are passed with the faeces, together with some of the eggs from the uterus.

The further development of the eggs of the *tænia solium* takes place in another "host," almost always in the hog. Hogs are infected by eating faeces, offal, etc., containing *tænia* eggs. The thick shell of the eggs is dissolved in the hog's stomach, and the free embryos pierce the walls of the stomach and intestines and travel with the blood-current, or through the tissues, into the different organs, especially into the muscles. Here they develop, in two or three months, into cysts something larger than a pea, from whose walls a newly developed *tænia*-head arises, a so-called *scolex* (nurse). These cysts are termed worm-cysts, measles, or *cysticerci cellulosa*. They live from three to six years; then they die and become calcified. If a *cysticercus* gets into a man's stomach from his eating raw or imperfectly cooked ham or pork, a new and complete *tænia* sprouts from the *scolex*, which forms mature segments in three or four months.

We usually find only one tape-worm in a man, but several specimens have been seen at the same time in the same intestine. The length of a tape-worm's life is not certainly known, but it has happened that some persons have lodged the same tape-worm for ten or fifteen years.

Although the fully developed *tænia solium* is seen only in man, as we have said, the *cysticercus cellulosa* has been found, in rare cases, in dogs, rats, and monkeys, as well as in hogs. It is a particularly important fact that the *cysticercus*

FIG. 40.—Comparative view of the eggs of some of the commoner intestinal parasites. 1. Egg of *distoma hepaticum*. 2. *Distomum lanceolatum*. 3. *Tænia solium*. 4. *Tænia mediocanellata*. 5. *Bothriocephalus latus*. 6. *Oxyuris vermicularis*. 7. *Trichocephalus dispar*. 8. *Ascaris lumbricoides*.

*cellulosa* itself may also occur, as such, in man. If tape-worms or mature segments get into a man's stomach in any way, probably by auto-infection, by the finger, etc., the embryos travel into other organs. *Cysticerci* are often found in men, singly or in groups, especially in the skin, the brain, the eye, and the muscles. There is a special form of *cysticercus* of the brain, in which we find a whole chain of cysts, like a cluster of grapes, but sterile, the so-called *cysticercus racemosus*.

2. The *tænia mediocanellata*, or *tænia saginata* (from *saginare*, to fatten), is even more common than the *tænia solium* in many parts of Germany. It is longer than the *tænia solium*, being about three or four metres long, and its individual

joints are, on the whole, broader and thicker. The head (Fig. 41) has also four prominent cup-like suckers, but it has no crown of hooklets. The mature segments differ from the proglottides of *tænia solium*, in that the central uterus sends off many more (twenty to thirty) side branches, which divide dichotomously, and not like a tree. The sexual opening is also on the side (Fig. 42, a).

FIG. 41.—(FROM HELLER.)  
Head of *tænia medio-canellata*.

FIG. 42.—(FROM HELLER.)  
*Tænia medio-canellata*.  
Mature segment.

The life-history of the *tænia medio-canellata* is, on the whole, like that of the *tænia solium*. The *tænia medio-canellata*, however, throws off single mature segments much more frequently than the *tænia solium*. These segments are found in the faeces, and here they often exhibit a crawling motion. The cysticercus of *tænia medio-canellata* does not inhabit pork, but beef, so that the infection of man by this tape-worm comes from eating raw beef. In man the cysticercus of *tænia medio-*

*canellata*, which is somewhat smaller than the cysticercus *cellulosæ*, has never yet been observed.

3. The *bothriocephalus latus* occurs in Holland, Switzerland (Geneva), Pomerania, East Prussia, Hamburg, and Russia (the German Baltic provinces). It has not yet been observed in middle Germany. It is the largest tape-worm; it may be six or eight metres long, and sometimes has over four thousand joints. The head of the *bothriocephalus* (Fig. 43) consists of a little club-shaped swelling, with two slit-like depressed suckers on the sides. A long, thread-like neck joins the head to the youngest segments. The full-grown segments (Fig. 44) are short, but are distinguished by their great breadth. The largest segments measure in length about three or four millimetres, and in breadth ten or twelve, but the last joints are longer and are not so broad, so that they have an approximately quadrilateral form.

a

FIGS. 43 and 44.—(FROM HELLER.)  
FIG. 43.—Head of *bothriocephalus latus*.  
a. Lateral view, enlarged. b. Natural size.  
FIG. 44.—*Bothriocephalus latus*. Mature segment.

The uterus consists of a very tortuous canal in the center. The sexual orifice does not lie on one side, as in the *tænia*, but in the middle of the abdominal surface, nearer the anterior border of the segment than the posterior. The eggs (*vide supra*, Fig. 40, 5) are of an oval form, and have a hood-shaped lid at one end. They are to be found in almost every dejection of persons affected with a *bothriocephalus*.

Single joints of the tape-worm are not passed with the stools, but portions of the worm, several feet long, come away from time to time, especially in the spring and autumn.

The noteworthy life-history of the *bothriocephalus* has been made perfectly clear by Braun, of Dorpat. The eggs develop only in fresh water. The embryo (Fig. 45), which is formed in them in a few months, and is provided with six hooklets and with vibrating cilia, is swallowed by fishes, especially by pike and eel-pouts, and develops in their muscles and internal organs into cysticerci. The infection of man with *bothriocephalus* comes from eating such fish containing cysticerci.

**Symptoms and Diagnosis.**—In many cases tape-worms are lodged in the intes-

tines without causing any morbid symptoms. We can recognize their presence only by occasionally finding the joints in the dejections.

In other cases, however, tape-worms cause a list of disturbances which are often exaggerated by anxious, hypochondriacal, and nervous persons, but which ought not to be too little regarded. The symptoms are referred chiefly to the intestinal canal. Sometimes there is quite severe abdominal pain, which may assume a colicky character. The patient also frequently complains of irregularity of the bowels, and of occasional diarrhoea, which alternates with constipation. Many general symptoms are also added to those mentioned—loss of appetite, or at times marked voracity, general languor, disinclination to work, mental disturbance, depression, etc. We can see that, under such circumstances, the general health may suffer considerably.

We must also mention a number of symptoms which probably owe their origin to abnormal reflex processes. Among these we sometimes see marked salivation, tickling in the nose, dilatation of the pupils, palpitation, vomiting, headache (migraine), etc. In some cases even severe spasms, and choreic conditions, have been referred to the presence of tape-worms in the intestinal canal, but it is hard to decide how far such a supposed connection can really be regarded as justified.

Although many of the symptoms mentioned may arouse suspicion as to the presence of a tape-worm, the diagnosis can be made only by finding the joints or eggs of the tape-worm in the dejections. In many cases the patient himself brings some of the segments found by him in the dejections to the physician, but in judging of them a certain caution is always necessary, since shreds of mucus, remains of food, etc., are quite frequently presented to the physician, under the idea that they are segments of tape-worm. If possible, we should take pains to decide definitely, from the segments laid before us, the species of tape-worm, which is usually not a difficult task if we follow the anatomical description given above. If we spread out the pieces of tape-worm on a microscope slide, the thicker, fatter segments of the *tania mediocanellata*, with its many-branched uterus, may usually be distinguished without difficulty from the more tender and more translucent segments of the *tania solium*, with a smaller number of lateral branches to its sexual apparatus. The statement of many patients that single segments of tape-worm come from them at other times than when at stool, and that they find them on their underclothing, almost always points to the presence of a *tania mediocanellata* in the intestine.

If we suspect a tape-worm, without having secured the certain evidence of segments in the dejections, it is a good plan to give the patient a mild cathartic, like castor-oil, or a dose of boiled pumpkin-seeds, since after this, if the intestine harbors a tape-worm, single portions of it almost always come away.

**Treatment.**—The "tape-worm cures," which are recommended in so great a number that we can by no means mention all of them here, but only the most important and the most serviceable, aim at killing or benumbing the worm, and then at removing it from the intestine *in toto* by cathartics.

We usually begin with a so-called "preparatory treatment." This is to cleanse the intestine, especially the large intestine, from old faecal masses, in order to prepare as free a passage as possible for the worm. For this purpose we give the patient a mild laxative, or, better still, a large enema of cold water. We also forbid

FIG. 45.—Embryo of *bothriocephalus latus*, with its ciliated coat. (LEUCKART.)

for a day or two the use of vegetables, black bread, etc., and prescribe instead a limited diet of white bread, some meat, milk, and coffee. It is a wide-spread practice to take during the preparatory treatment certain articles of food to "make the worm ill." Among these a salad of finely chopped and very salt herring with onions and garlic is especially recommended. A similar action is also ascribed to strawberries, cranberries, and bilberries. Hence, on the day, and especially on the afternoon, before treatment, we have the patient take a large amount of the articles of food mentioned, such as herring salad.

On the next morning, after everything has been prepared, after the bowels have moved the night before, etc., the patient takes no breakfast, or only some strong sweet *café noir*. Then he takes the special anthelmintic, and in one or two hours, if he feels a great pressure in the abdomen, he also takes a few spoonfuls of castor-oil or rhubarb.

The number of ténicides recommended is, as we have said, very great. At present the following are most in use:

The bark of pomegranate-root (*cortex radiceis Punice granati*) is one of the most efficient remedies. We usually prescribe it in combination with the ethereal extract of male fern, in the following prescription:

R Granati radiceis corticis.....  $\frac{3}{4}$  iv-v (grm. 120-150);

Aquæ..... O ij (grm. 1,000).

Macerate for twenty-four hours, and boil until it is reduced to  $\frac{3}{4}$  v (grm. 150).

Add: Oleoresinæ filicis..... gr. lxxv (grm. 5).

The whole amount is to be taken in three or four doses as near together as possible. In order to obviate the bad taste of the remedy and to increase the action by introducing a larger amount at once, it has been recommended to introduce the whole amount of a still stronger decoction of pomegranate-root at once into the stomach by means of an œsophageal tube. As a rule, it is well to avoid this procedure.—To be recommended is also the tannate of pelletierine, prepared from the pomegranate-root. It is almost tasteless, and in doses of 8-25 grains (grm. 0.5-1.5) is said to be a very certain ténicide. Usually one obtains excellent results with male fern. Two to two and a half drachms (grm. 8-10) of the extractum filicis (P. G.) must be given [or one and a half to two fluidrachms of the oleoresin]. It may be put in gelatine capsules on account of its bad taste.

Another remedy, which has often proved successful, is koussou-flowers. We give three or four powders, each containing seventy-five grains (grm. 5) of powdered koussou-flowers, in white wine, giving a glass of wine containing one powder about every half-hour. Rosenthal's "koussou tablets" are more agreeable to take and are very good, but they are more expensive. Twenty of these, of fifteen grains each (grm. 1), may be taken without danger within an hour with *café noir* or lemonade. During the period of treatment the patient must lie as quiet as possible in order to avoid vomiting. Up to the present time we have not had sufficient experience of the koussine or kosseine, prepared from the alcoholic extract of koussou-leaves, which is said to be very efficient in doses of thirty to forty-five grains (grm. 2-3).

Of the other remedies we may mention kamala, one to three drachms (grm. 5-10) of the powder in wine or water, and oil of turpentine, one or two ounces (grm. 40-60) in two doses in milk—an efficient but rather dangerous remedy in these doses—and picro-nitrate of potassium. We may also prescribe male fern in powders of a drachm (grm. 4) each, taking three or four powders within an hour.

The treatment is to be regarded as absolutely successful only when we find the

head of the tape-worm, as well as its joints, in the patient's dejections. We may best search for the head in the faeces by diluting the dejection with water, stirring it repeatedly, and pouring off the water. The tape-worm then remains at the bottom of the vessel.

Every tape-worm treatment is rather drastic, and hence it is well, after the treatment is over, to recommend the patient to be prudent in his diet, and to be careful about his digestive tract for some time. In persons who are very weak, or who have some other disease, we do not willingly undertake to remove a tape-worm without urgent reasons; but in people who are otherwise healthy it is always well to get rid of a tape-worm, even if it causes no severe symptoms. Of course only the *tania solium* is attended with the serious danger of the cysticerci invading the brain (see diseases of the brain). The best time for undertaking a treatment is when joints or large pieces of the worm come away quite frequently of their own accord. We should never prescribe a treatment on the mere statements or suspicions of the patient. We must always convince ourselves with complete certainty of the presence of a tape-worm in the intestine.

We must finally mention that the only efficient prophylaxis against acquiring a tape-worm lies in entirely avoiding the use of raw or half-cooked beef or pork. The more widely spread the taking of raw meat is, as in Abyssinia, the more common are tape-worms in man. Certain callings, like those of cooks and butchers, are also especially exposed to infection.

## 2. Round-worms.

(*Ascaris lumbricoides*.)

**Natural History.**—*Ascarides* are pale-reddish, cylindrical worms, pointed at both ends, with the sexes in different individuals. The females are thirty or forty centimetres long, the males about twenty-five. At the cephalic end of the worm are found three lips furnished with fine teeth. The tail is straight in the females and curved in the males. In the female sexual organs (Fig. 46) sixty millions of eggs may develop, at a rough estimate. These eggs are often found in the faeces of people who have round-worms in their intestines (see Fig. 40, 8). They have a great capacity of resisting external influences, and a worm-like embryo develops in them in a few months. Their further fate, and the form and manner in which infection usually takes place in man, are not yet accurately known. It is probable the parasites are spread without any intermediate host by direct ingestion of the eggs which contain the embryos.

The round-worms inhabit chiefly the small intestine. In severe vomiting they often reach the stomach and are vomited up. In individual cases they have been found in the bile-ducts, in the air-passages, and,

FIG. 46.—(From HELLER.)—*Ascaris lumbricoides*. Female, 143 millimetres long. a. Vagina. b. Intestine. c. Boundary between the uterus and oviducts. d. Longitudinal bands. e. Coil of oviducts and ovaries.

after perforation of the intestine, in the abdominal cavity. The number of round-worms existing at the same time in the intestines may be very considerable. We find them most commonly in children and in adults from the lower classes. Round-worms have been repeatedly observed to crawl out of the anus, the mouth, or the nose of children during sleep.

The round-worm is also common in hogs and cattle as well as in man.

**Symptoms.**—In general, the round-worms are innocent parasites, which may exist in large numbers in the intestines without any bad results. Exceptionally they cause symptoms similar to those ascribed to tæniæ—abdominal pain, languor, itching of the nose, burning in the eyes, etc.—symptoms which are all ambiguous, and whose definite connection with the presence of round-worms it is hard to make out. The cases recorded in literature are quite numerous in which severe nervous symptoms have been caused by round worms and have disappeared after the removal of the parasites. However cautious we may be in accepting such statements, nevertheless their credibility can not be wholly denied. We would mention especially convulsions, epileptiform seizures, choreic and cataleptic conditions, contractures, and temporary mental disturbances, which are claimed to be excited by ascarides. Milder nervous attacks—like headache, vertigo, dilated pupils, and chills—are quite frequently seen in children with ascarides.

In some cases the presence of ascarides may excite much more severe symptoms by unfortunate accidents, as, for example, sudden suffocation from the entrance of a round-worm into the larynx. When a very large number of round-worms have been present in the intestine, severe symptoms of intestinal stenosis have been observed from their rolling together into a ball. If a round-worm crawls into the bile-ducts, it may give rise to jaundice, and even to the development of an abscess of the liver. In the abscesses of the anterior abdominal wall, usually termed "worm abscesses," the round-worms probably play a purely accidental part. We have to do in such cases with perityphlitic abscesses or with inflamed herniæ, which have perforated externally, by which the round-worms which are accidentally found in the intestines pass out, without having any causal relation to the abscess.

**Treatment.**—The oldest and most approved remedy against ascarides is worm-seed—santonica. This is best given in the form of an electuary—santonica, a drachm (grm. 5); jalap, fifteen grains (grm. 1); and syrup, an ounce (grm. 30), to be taken in three doses—in combination with a cathartic. Of late, worm-seed, on account of its bad taste, has been almost wholly replaced by santonin, which is derived from it. This is prescribed in one- or two-grain (grm. 0.05–0.10) powders, or still more frequently in the form of santonin troches ("worm-tablets"), which may be had of any apothecary. It is well to give santonin also in connection with a cathartic, like calomel. We let the patient take one or two doses of santonin in the morning for three days, and on the fourth we give a cathartic. Severe symptoms of poisoning—spasms—have been seen only occasionally from the careless use of it. Milder symptoms, like a yellowness of the urine and conjunctivæ, and xanthopsia, or seeing everything as yellow, are somewhat more frequent.

### 3. *Oxyuris vermicularis*.

(*Seat-scorma*. Pin-worms.)

**Natural History.**—The oxyures are little round worms, the females ten or twelve millimetres long, the males only three or four (see Figs. 47 and 48). The eggs, when they reach the human stomach, develop very rapidly. The embryos, set free, collect in the small intestine and later in the cæcum, where they soon

become mature. The impregnated female usually crawls down into the rectum, deposits her eggs there, and either crawls out of the anus herself, or, like the male, is evacuated with the feces. The whole development of the oxyuris occupies about a fortnight. The total number of oxyures present in the intestine at the same time may be very considerable, so that "the whole mucous membrane of the large intestine is covered with them like fur."

The infection by the eggs of the oxyuris probably takes place, as a rule, from one man to another, since the eggs stick to the hands (in scratching the anus), and are thus communicated to food, bread, fruit, etc. In children and dirty adults auto-infection may often be repeated in an analogous manner.

**Symptoms and Treatment.**—The oxyures found in the upper portions of the intestine and in the cæcum cause no symptoms whatever, but in the lower part of the rectum their presence causes local symptoms, especially a very severe feeling of itching and burning in the anus, which makes the child constantly scratch and dig with his fingers. This itching of the anus is most severe at night in bed. In girls the oxyures frequently travel into the vagina, by which an intense itching is also set up there, which sometimes leads to masturbation. In some cases in boys and men oxyures have been found to be the cause of abnormal sexual irritation.

The diagnosis of oxyures is not difficult. Our attention is called to the itching of the anus, and we look for worms. Single worms are easily found in the dejections, and often on the skin about the anus. The diagnosis is made more certain by finding the eggs (Fig. 40, 6) in the feces under the microscope.

Treatment can remove the oxyures from the rectum with ease, but only with difficulty from the upper portions of the intestine, especially from the cæcum and the vermiform appendix. Santonin is generally used, but we must also prescribe large enemata of cold water and cathartics internally. Instead of ordinary water we may use soap-suds, vinegar-water, and, in severe cases, a weak solution of corrosive sublimate (1 to 10,000) in the enemata. The itching of the anus is relieved by rubbing on a little mercurial ointment.

[Enemas containing infusion of quassia, alum, eucalyptol, tannin, etc., are much in use. A plain enema should be given first, to unload the rectum and clean the membrane as far as possible, so that the anthelmintic may reach the worms when introduced.]

FIG. 48. — (From HELLER.) *Oxyuris vermicularis*, enlarged. a. Mature female, not yet impregnated. b. Male. c. Female containing eggs.

4. *Anchylostomum duodenale*.*(Dochmius* *vel* *Strongylus duodenalis.)*

The *anchylostomum duodenale* is a worm first observed in upper Italy and in Egypt, which, singly or in large numbers, inhabits the upper portion of the small intestine, especially the duodenum, but also the jejunum and ileum. The male is six to ten millimetres long, the female ten to eighteen. At the cephalic end (Figs. 49, 50) is found a bell-shaped mouth-capsule, which is provided with two

FIG. 49.

FIG. 50.

FIG. 49 — *Anchylostomum duodenale*. Natural size. a. Male. b. Female.

FIG. 50 — (From HELLEB.) *Anchylostomum duodenale*, enlarged. Head with bell-like mouth.

small teeth on its dorsal edge, and four larger curved teeth on its ventral edge. With this sucking and biting apparatus the worm fixes itself firmly, like a wet cup, on the intestinal mucous membrane, and is nourished by the blood which it sucks out. The places in the intestine to which an *anchylostomum* has fastened may be recognized in the cadaver as little ecchymoses. The worms sometimes bore completely into the inner part of the mucous coat.

If the intestine harbors many *anchylostoma*, the small but constant loss of blood caused by them is not without influence on the organism. The symptoms of a severe anæmia gradually develop. Griesinger first made the discovery, in the year 1854, that the disease long known by the name of "Egyptian chlorosis" was caused by the *anchylostomum duodenale*. Since then confirmatory observations have been made in many parts of the tropics. Of late years the *anchylostoma* disease has become well known, because it occurred with great frequency among the Italian laborers employed in building the St. Gothard tunnel. In Germany, too, cases have repeatedly been detected, especially among brick-makers in the Rhineland and elsewhere, who work in wet clay-pits. The infection probably takes place chiefly from drinking impure, muddy water, in which the eggs of the *anchylostomum* are found.

The symptoms of the disease consist of a gradually increasing general anæmia, for which no special organic lesion can be made out objectively as a cause. The patient also suffers from very great general weakness and languor, constraint in breathing, palpitation, headache, oedema, etc. The changes

in the blood (oligocythæmia, poikilocytosis) are precisely similar to those seen in pernicious anæmia. The disease may last for months, or even years, and it often ends fatally, if it be not recognized and treated in time.

Leichtenstern has made numerous and accurate observations with regard to the brickmakers of Cologne. He states that no symptoms are observed for three or four weeks after infection with the embryos of the *anchylostomum*. Some five or six weeks after infection, when the parasites become sexually mature and breed, there appear bloody diarrhoea, intestinal colic, and accompanying progressive anæmia. At this time there is probably more shifting about of the parasites in the intestine, while they later become more fixed. This explains why the disease evinces a more acute and severe character at first, and then takes on the form of a chronic anæmia, with great diminution or cessation of the bloody stools.

The diagnosis is easy if we only think of the possibility of *anchylostoma*. Many eggs may be found in the feces, without great trouble; these are quite like the eggs of *ascaris lumbricoides*, only they are a little smaller. After using

cathartics, the full-grown worms have often been found in large numbers in the patient's dejections.

If the trouble is correctly diagnosticated, treatment will usually give good results. We prescribe the same anthelmintics as for the other intestinal parasites, especially male fern in large doses, and also cathartics and enemata. In this way we often succeed in removing the parasites entirely from the intestinal canal, and thus bring about a complete cure, even in severe cases. Less certain in its effects is doliarina (made from *ficus doliaria*), of which the dose is one drachm (grm. 4.0) three times a day.

### 5. *Trichocephalus dispar*.

(*Whip-worm*.)

The *trichocephalus dispar* is a worm four or five centimetres long, whose anterior part is very thin, but whose posterior part is decidedly thick (Fig. 51).

The chief dwelling-place of the *trichocephalus* is the cæcum, where it is often found singly or in large numbers. It seems to have no clinical significance. At the most, if present in very large numbers, it may give rise to faecal impaction, typhlitis, etc., but up to the present time no such occurrence has been actually demonstrated.

FIG. 51.—(From HELLER.) *Trichocephalus dispar*.

## SECTION VI.

### DISEASES OF THE PERITONEUM.

#### CHAPTER I.

#### ACUTE PERITONITIS.

**Ætiology.**—There are two ways by which inflammatory agents most frequently reach the peritoneum: one is from the gastro-intestinal tract, and the other—in women—is from the genitals.

All the diverse forms of ulceration which attack the digestive canal may involve the serous layer. In such a case an inflammation arises which is at first limited, but may under certain circumstances become more extensive. This inflammation may be regarded as analogous to that of the pleura in pneumonia; but the anatomy of the stomach and intestine is such that very often an ulcer in their walls ends in a complete perforation. If this occurs, the inflammatory germs contained in the primæ viæ at once escape into the peritoneal cavity and there excite an inflammation; which, from the specific character of its cause, is invariably purulent, and very frequently is at the same time septic or ichorous. The possibility of a peritonitis due to perforation, as a result of the various ulcerative processes of the stomach and intestines, has been frequently referred to in the previous sections of this work. Thus, it may occur in simple ulcer and in ulcerating cancer of the stomach; in typhoid, tubercular, or dysenteric ulceration of the intestine; in ulceration of the intestine above intestinal stenoses of many varieties; and in the small ulcers of the vermiform appendix due to the pressure of hard substances.

The female organs of generation are the other frequent source of peritonitis. In labor and premature delivery the genital tract is often directly infected. The infection may also occur, although much less frequently, at other times; for example, during menstruation. The various forms of inflammation which are thus set up, including endometritis, metritis, and parametritis, may in several different ways reach the peritoneum and excite peritonitis. A septic inflammation of the endometrium may involve the peritoneum by direct extension up the Fallopian tubes. In other cases it is through the lymph-vessels that a purulent metritis or parametritis spreads to the peritoneum. The larger parametritic abscesses may break into the peritoneal cavity. It is to be particularly noticed, however, that in many cases of septic puerperal peritonitis the uterus and its appendages are in a perfectly normal condition, having served merely as a gateway to the inflammatory agents without suffering any harm themselves.

Besides these two chief sources of peritonitis, numerous others are possible, although much less frequent.

Sometimes peritonitis is due to an extension of inflammation from other abdominal viscera. Hepatic abscess, suppurating hydatid cysts of the liver, ulcer of the biliary ducts, splenic abscess or infarction, purulent nephritis or pyelitis, abscess near the bladder or in the prostate, suppurating ovarian cysts, tubal pregnancy, psoas abscess, and Pott's disease—all these may produce peritonitis, either by direct extension or by perforation.

It is worthy of note that peritonitis may occur as a sequel of pleurisy. The pleural and peritoneal cavities are directly connected by the lymph-vessels of the diaphragm; and empyema as well as tubercular pleurisy (see next chapter) may spread to the peritoneum.

Penetrating wounds of the abdomen are a fruitful source of acute peritonitis. Surgical operations upon abdominal organs come under the same head. A large number of laparotomies proved fatal before Listerism was introduced, because the inflammatory germs thus admitted excited a diffuse septic peritonitis. Even tapping the abdomen for ascites may cause acute peritonitis if the trocar is not aseptic. Abdominal injuries, in which the walls are not penetrated, very rarely, if ever, give rise to peritonitis. One way in which they have been said to produce it is by exciting internal hæmorrhage. In the new-born, peritonitis sometimes results from infection through the navel.

Two diseases still remain to be mentioned, in the course of which acute peritonitis may be developed, although the occurrence is a rare one—acute articular rheumatism and nephritis. It may either be one of the symptoms of these diseases or an independent complication. We are somewhat in doubt as to how it arises. In acute articular rheumatism it must be regarded as analogous to the pleurisy and pericarditis which occur in the course of this disease, for they also involve serous membranes. We should likewise bear in mind the possibility that the inflammation may extend from the pleura to the peritoneum through the lymphatics. Acute peritonitis has now and then been observed in the various forms of nephritis, both acute and chronic, inclusive of amyloid disease. It usually proves fatal in these cases. Possibly the retention of urinary impurities in the blood plays some part in the development of this form of peritonitis.

**Pathology.**—Like the analogous inflammations of the pleura and pericardium, peritonitis is divided into different varieties according to the character of the inflammatory exudation. The nature of the exciting cause of most cases of peritonitis is such that by far the most frequent variety is the fibrino-purulent. If the process involves the entire peritoneum—that is, if there is a “diffuse general peritonitis”—we generally find upon opening the abdomen that the parietal layer of the peritoneum and the outer surface of the intestinal coils are distinctly reddened,

from marked vascular injection. There may even be small ecchymoses here and there. The serous membrane is clouded, a result partly of desquamation of its endothelium, and partly of the more or less abundant fibrinous exudation which covers the peritoneum with a sheet of coagulated fibrin. Very often the coils of intestine have formed numerous adhesions with one another (compare pleuritic adhesions). In cases of brief duration these can still be easily broken up, but after a prolonged illness they are extremely firm. There is usually also some free, fluid, fibrino-purulent exudation in the abdominal cavity. Its amount varies greatly. Sometimes there is only a small quantity of opaque fluid in the dependent portions of the cavity; sometimes there are many quarts, causing great distention of the abdomen. The exudation seldom inclines to a sero-purulent character. It is usually predominantly purulent. Very often the purulent exudation undergoes decomposition into the offensive sanious fluid of septic peritonitis. This is particularly apt to occur when the disease originates from an intestinal perforation or from puerperal poisoning. The perforation through the walls of the intestine is sometimes so large as to admit considerable amounts of intestinal gases and feces into the peritoneal cavity. It is also possible that the putrefaction of peritoneal exudations may generate offensive gases. In rare instances the exudation is hæmorrhagic; but most cases of hæmorrhagic peritonitis do not belong here, but come rather under the tubercular form (*vide infra*).

In severe and protracted cases of peritonitis the intestine is involved to a certain extent. There is a collateral inflammatory œdema of its walls, causing sometimes a considerable increase in thickness, while at the same time they may be non-resistant and easily torn. The weakness of the muscular layer of the intestine may amount to complete paralysis, and thus permit excessive intestinal tympanites, either diffuse or local.

Milder forms of general peritonitis with sero-fibrinous, or chiefly serous, exudation are relatively infrequent. Under this head would come certain apparently primary and usually chronic cases with favorable issue, and also the peritonitis which sometimes occurs as a sequel of an ascites which has existed for some time (see next chapter). Probably also in those rare cases where a peritonitis arising in the course of acute rheumatism has ended in recovery, the exudation has been sero-fibrinous.

We have spoken thus far of diffuse general peritonitis, but cases are not rarely seen of circumscribed or "encapsulated" peritonitis. Here, also, we have mild varieties with fibrinous exudations on the one hand, and on the other purulent inflammation. The milder inflammation is a result of the extension of the most varied forms of inflammation in neighboring organs. Thus, deep intestinal ulcers, for example, give rise to a mild circumscribed inflammation of the corresponding portion of the serous layer. A similar condition results from superficial splenic infarctions; from various hepatic diseases, when they reach the surface of the liver; and from numerous pathological conditions of the female genitals. In many of these cases the peritonitis takes a chronic course and leads to adhesions, and hence is called adhesive peritonitis.

Circumscribed purulent peritonitis has precisely the same ætiology as the general form, with this single difference, that firm adhesions are quickly formed around the spot whence the inflammation proceeds, limiting it and preventing it from involving the entire peritoneum. It occurs most frequently as a purulent perityphilitis (*q. v.*) consequent upon perforation of the vermiform appendix; and also as pelvic peritonitis, which is a possible sequel of most of the forms of puerperal inflammation to which the uterus and its appendages are liable. It may also follow perforative gastric or intestinal ulcer, hepatic abscess with perforation, and analogous affections. So-called sub-diaphragmatic abscess is a form of encapsulated purulent peritonitis.

Histologically considered, acute peritonitis is perfectly analogous to the inflammatory processes which attack other serous membranes. The endothelium becomes degenerated, and, for the most part, is cast off. There is an exudation from the blood-vessels of a fibrinous fluid, which is partly coagulable, and with this exudation round cells escape in greater or less abundance. In the further progress of the disease there is an inflammatory new growth of vascular connective tissue, which probably originates chiefly from the endothelium and the permanent tissue-cells, but, according to some, starts in part also from the wandering cells. The new formation of blood-vessels certainly seems to be chiefly due to budding from the capillaries of the serosa. Thus arise the adhesions of connective tissue and the false membranes found in chronic cases between the different coils of intestine. They lead in process of time to marked thickening and retraction of the omentum and mesentery (*peritonitis deformans*). Most cases of purulent peritonitis prove fatal in the early acute stage. If a case recovers, the exudation undergoes fatty degeneration, and its cellular constituents are thus disintegrated and then are absorbed.

The results of circumscribed purulent peritonitis are detailed in connection with the clinical history.

**Clinical History.**—1. *Acute General Peritonitis.*—The following description applies chiefly to the severe purulent form, the one by far most frequently met with. It occurs in most instances after perforation, in puerperal cases, and after external injuries, such as surgical operations. In most of these cases the peritonitis is a secondary disease, so that it must obviously be greatly modified in its general characteristics and behavior by the original trouble. In the first place, the onset is modified. Many cases of peritonitis due to perforation begin abruptly, the patient having been previously in perfect health. Thus, as already mentioned, the first indication of a gastric or duodenal ulcer may be given by perforation. Most cases of perforation of the vermiform appendix present equally sudden and unexpected symptoms.

There are many other cases where the symptoms of peritonitis supervene upon those of some grave disease already existing. For example, typhoid fever, intestinal tuberculosis or intestinal stenosis, may, by causing perforation, excite a peritonitis. Here the symptoms of this secondary disease may be more or less completely veiled by the other grave local and constitutional disturbances.

Again, an acute general peritonitis may, as we have already said, be the sequel to a local and circumscribed inflammation of the peritoneum. Thus, a purulent perityphlitis, or a purulent puerperal pelvic peritonitis, may finally become universal. In such unfortunate cases the change in symptoms is often gradual, and is not clearly pronounced.

We have now indicated certain variations from the general course of the disease; but, with these exceptions, almost every case of acute general peritonitis, whatever its aetiology, presents clinical symptoms which are so characteristic and typical that a general description of the disease will be both easy and advantageous.

The symptoms of acute peritonitis form two groups, the local and the constitutional. The latter are the result of the local disturbance acting upon the general condition of the patient.

Of the local symptoms, pain deserves to be named first. It is usually the earliest symptom; and, as the disease progresses, it is generally the excruciating abdominal pain which attracts most attention. The localization of the pain in the beginning of the illness may be of diagnostic value in doubtful cases, if such as to indicate the possible starting-point of the inflammation, for example, the vermiform appendix or a gastric ulcer. Later the pain extends over the whole

abdomen. As a rule, there are brief remissions followed by fresh exacerbations. The pain is aggravated by voluntary movements, by deep inspirations, and probably by intestinal peristalsis. The abdominal tenderness is often extreme in peritonitis, and is very characteristic. The gentlest palpation is torture, and often the slightest pressure of the bed-clothes is almost unbearable. Frequently the greatest tenderness is in the umbilical region.

Acute peritonitis seldom exists without pain. The exceptions to this rule are chiefly seen in patients who are extremely prostrated, and whose sensibility and intelligence are much impaired. Here the peritonitis itself may escape notice.

Physical examination of the abdomen greatly aids the diagnosis in many ways.

As a rule, the abdomen is distended. This is an early symptom, and gradually becomes more and more pronounced. It is due mainly to the intestinal tympanites, which we have already mentioned, and which sometimes becomes very great if the muscular fibers of the intestine are paralyzed. In the later stages the liquid effusion into the peritoneal cavity of course contributes to the prominence of the abdomen, but even then the distention is seldom so uniform or so broad as in ascites. In peritonitis, coils of distended intestine can often be recognized by their characteristic contour through the abdominal wall. In general, if the abdominal wall is yielding and thin, the peritonitic distention will be greater, so that it is most marked in puerperal cases, where the preceding pregnancy has rendered the walls lax. In a person with powerful muscles and tense abdominal walls the convexity of the abdomen is seldom great. In some cases there is no convexity whatever. The walls may be as hard as a board, and the abdomen flat or slightly concave. In such cases diagnosis may be difficult. Sometimes, again, the original retraction of the abdominal walls is succeeded by more or less distention of the abdomen.

Percussion over the distended intestinal coils yields a resonant and usually tympanitic sound. It is not till a considerable amount of liquid effusion has collected that there is dullness, most marked in the dependent portions of the abdomen. If there is much tympanites, however, quite a large effusion may exist without being detected on percussion. Usually there is too much pain to permit a careful examination of the change of dullness consequent upon change of decubitus. In general, the numerous adhesions between the separate coils of intestine not infrequently interfere with the free motion of the peritonitic exudations.

Percussion not only gives information about the existence of a liquid, purulent effusion, but is also of value in determining the level of the diaphragm, as affected by abnormal abdominal distention. The upper limit of hepatic dullness is raised to the fifth or even the fourth rib. The heart is also pushed up. There is a tympanitic resonance above the margin of the ribs on the right side. The area of hepatic dullness is not only displaced upward, but is also evidently diminished. This is due in part to coils of distended intestine overlapping the anterior edge of the liver, and in part to the organ being tilted upward in such a way that its area of contact with the anterior wall of the body is less than normal. Various authors formerly laid great stress upon the total disappearance of hepatic dullness, regarding it as a sure sign that gas has escaped from the intestine into the abdominal cavity. The inference is not always correct. The liver may be displaced backward by coils of intestine, and hepatic dullness be thus abolished, although there is no air free in the peritoneal cavity.

If there is a considerable effusion, it is possible, as in ascites (*q. v.*), to get a sensation of fluctuation by gentle, quick palpation.

As a rule, auscultation of the abdomen does not throw much light on a case of peritonitis. In the distended coils of intestine we not infrequently hear all sorts of gurgling and splashing sounds. Sometimes we hear a peritonitic friction-

sound, coincident with the movements of respiration and due to the rubbing against each other of two rough surfaces under the impulse of the diaphragm. In particular this friction-sound has been repeatedly heard over the liver.

In almost every severe case of peritonitis there are gastro-intestinal symptoms.

As to the stomach, vomiting is the most frequent and important symptom. Vomiting is often seen early in the disease, and recurs frequently as the illness progresses. It sometimes is spontaneous, and sometimes follows the ingestion of food. If spontaneous, the vomitus consists of watery mucus, usually of a greenish tinge. Why vomiting is so prominent in peritonitis we do not know absolutely. Apparently it is in part a reflex action, excited by the inflammation of the serous membrane. Possibly the external pressure of the exudation also affects the stomach. It must be added that vomiting may be absent in acute peritonitis. This is seen when the patient is comatose, and sometimes also when the peritonitis has developed upon perforation of a gastric ulcer, because the contents of the stomach are thus emptied out through the hole in its walls. The vomiting usually is accompanied by frequent eructations.

Of the intestinal symptoms, the reader has already become acquainted with the tympanites, and also with the fact that it is due mainly to a paresis of the muscular fibers of the intestine. This same muscular weakness furnishes an obvious reason for the persistent constipation usually observed in peritonitis: but we may have diarrhoea instead, from increased peristalsis and secondary intestinal catarrh.

The pushing up of the diaphragm has a noteworthy effect upon the thoracic organs. The lower lobes of the lungs are compressed, so that considerable dyspnoea results. The heart is likewise crowded upward, so that the apex-beat is usually to be felt in the fourth intercostal space.

Every case of acute peritonitis that is at all extensive has marked constitutional effects. These are in part the result of the wakefulness due to pain, and the restlessness and fever. But in all probability there are also decided reflex inhibitory influences, originating in the irritation of the peritoneal nerves and affecting chiefly the heart, just as Goltz in his well-known experiment killed a frog by blows upon the abdomen. There is no other disease, except internal strangulated hernia—and the effect of that is perfectly analogous—which produces general collapse so quickly as does peritonitis. The countenance is rapidly altered, the cheeks fall in, and the eyes become hollow. The nose grows sharp and cool, the lips dry and cyanotic. The skin of the extremities is also cool and bluish, as a result of impaired circulation. The patient is extremely feeble. The chief cause of all these symptoms is the excessive weakness of the heart. The peritonitis has hardly begun before we find the pulse small and soft. In many severe cases the pulse finally becomes almost imperceptible. At the same time the pulse-rate increases, as is usual in collapse from any cause, so that 120 to 140 beats per minute is not an exceptional rapidity.

The temperature varies greatly in different cases. It may be high in the rectum, although the skin feels cool. Still, very high fever is not usual; and there are often considerable remissions. We even frequently observe the subnormal temperature of collapse. The number of respirations per minute is usually 30 to 40. This increased rate is due not only to the compression of the lower lobes of the lungs, but also to the pain caused by full inspirations and to the impeded circulation.

The intellect remains in most cases almost unimpaired to the end. There may exceptionally be mild delirium, or an approach to stupor, toward the close.

The course of acute general peritonitis in the great majority of cases is unfavourable.

vorable. With the appearance of the grave symptoms just depicted the prognosis becomes almost hopeless. The course of the disease is also comparatively rapid. Marked variations in the intensity of the symptoms are infrequent. The grave local and constitutional symptoms persist, and, as a rule, the patient dies at the end of a few (two to six) days. Still, it is not well to make general dogmatic statements as to the clinical history, for the ætiology of each individual case impresses upon it individual characteristics. A peritonitis resulting from gastric or intestinal perforation is usually quickly fatal. The same is true of almost all cases of puerperal septic peritonitis. In a few cases, however, the inflammation is limited, by the encapsulation of the exudation. These may finally end in recovery through perforation of the abdominal walls or perforation into the intestinal canal. Now and then an acute general peritonitis may assume a chronic form. The effusion is mostly reabsorbed, and the newly-formed adhesions and false membranes contract into firm bands of connective tissue. The liver, spleen, and other abdominal viscera acquire a tough coating of connective tissue. The omentum and mesentery are shortened and thickened. Indeed, the omentum may roll itself almost completely up. Although the clinical symptoms become less severe, weakness usually persists, with gradual exhaustion and death. Often the intestine is so bent or pinched as to give rise to grave symptoms from stenosis.

Recovery from acute general peritonitis is very exceptional. If seen, it is usually in mild cases, such as sometimes occur after menstruation, abortion, or labor. Peritonitis as a complication of acute articular rheumatism is a very rare event. Its termination is generally favorable. In all cases of this kind the inflammation is probably not purulent, but sero-fibrinous.

2. *Acute Circumscribed Peritonitis*.—The local symptoms of this are essentially the same as we have just ascribed to the general form; except that, a smaller extent of tissue being involved, they are correspondingly limited. The pain and tenderness are confined mainly to one region, but its boundaries are never sharply defined. On palpation of this region, we find an increased resistance which is sometimes almost like that produced by a tumor. If there is an encapsulated effusion, we may detect fluctuation, particularly if the abscess is going to point outward. On percussion over the affected spot, there is either dullness or a muffled tympanitic resonance.

The constitutional symptoms are likewise those of general peritonitis, only usually less severe. Reflex vomiting does occur, but is seldom so persistent as in the diffuse inflammation. The physical weakness and symptoms of collapse are decided, but do not usually become extreme. There is generally an irregular fever, which may now and then assume an intermittent, pyæmic character. Most cases run a chronic course. If the illness be very much prolonged, death may finally ensue from general debility. Recovery is possible if the pus can be let out. This may be accomplished either by the surgeon or by Nature. Spontaneous discharge of the abscess may take place through the abdominal walls, into the intestine, or even, in rare instances, through the pleura into the lungs. But if the pus finds its way into the general peritoneal cavity, the peritonitis becomes diffuse and causes death.

To describe in detail each separate variety of circumscribed peritonitis would occupy too much space, and would also lead to useless repetitions. We have already spoken at some length of one especially important form—namely, perityphlitis. Perimetritis and pelvic peritonitis are chiefly puerperal affections, and are fully discussed by writers on gynæcology.

Abscesses which are very deeply situated—as, for instance, behind the stomach or in front of the spinal column—may prove very difficult to diagnose, being

so far out of reach. Sub-diaphragmatic abscesses containing air deserve a brief mention (*pyo-pneumothorax subphrenicus*). They are sometimes observed as a result of perforation of the stomach or transverse colon. Lying between the liver and the diaphragm, they crowd the latter upward, and are liable to be mistaken for pyo-pneumothorax. Sub-diaphragmatic abscesses containing no air also occur, originating in the liver or spleen. Finally, there is a rare form of circumscribed purulent peritonitis to be noted, to which children seem especially exposed. It declares its presence by a painful fluctuating tumor above the left groin, which usually points into the rectum and ends in recovery.

**Diagnosis.**—The diagnosis of peritonitis is in many cases an easy matter, when we have the characteristic symptoms of tenderness and tympanites, vomiting, and collapse. Often the starting-point of the inflammation is equally obvious, in cases of secondary peritonitis supervening upon some disease which we have already clearly recognized, such as typhoid fever, gastric ulcer, or puerperal diseases. But where the peritonitis is apparently primary, we must inquire carefully into the previous history and the earliest symptoms of the attack, in order to form even a surmise as to aetiology.

The diagnosis is sometimes greatly obscured by the fact that under certain circumstances very similar symptoms may be excited by other disorders affecting the intestines. Thus, in typhoid fever there may be great tympanites and grave constitutional symptoms, with abdominal pain, so that peritonitis may be diagnosed, while the autopsy, if there be one, discloses no signs of it. Deep ulcers of the intestine, however produced, may give rise to so great abdominal tenderness as likewise to simulate peritonitis. The grave symptoms of acute intestinal obstruction are often of such a character that it is impossible to determine whether the intestinal disorder has already induced a peritonitis or not. On the other hand, we have mentioned before that peritonitis attended by stupor and general depression may hide itself from the keenest eye, because the abdominal distention, tenderness, and other chief symptoms are absent.

It is not always easy to diagnosticate circumscribed peritonitis, even where the trouble is not deep-seated and therefore inaccessible. It is not infrequently mistaken for a new growth. In doubtful cases, a careful use of the aspirating needle is the more necessary, because the presence of an encapsulated peritonitic exudation in almost all cases demands operative interference. As to aetiology, it should be added that localized suppurative peritonitis, and less frequently chronic diffuse deforming peritonitis, may be due to actinomycosis (*vide* p. 274).

It is well to remember that a pregnant uterus and a distended and therefore painful bladder have each repeatedly been mistaken for peritonitis!

**Treatment.**—Although severe cases are generally almost hopeless, yet we must try to meet the symptomatic indications, and must do all in our power to promote a limitation of the process, if it be possible.

External counter-irritants or "revulsants" are seldom of much use. Painting with tincture of iodine and mercurial inunctions seem so utterly purposeless that they may be discarded. The local abstraction of blood can not be employed in an extensive peritonitis with constitutional prostration. It is only in a circumscribed peritonitis which is very painful, and where the general condition of the patient remains comparatively favorable, that local bleeding is to be considered. Under these circumstances, the application of eight to fifteen leeches sometimes causes decided abatement of the pain. The local application of ice to the abdomen is universally in vogue. It usually moderates the pain, and it may also have a beneficial influence in quieting peristalsis. Still, some patients can not bear ice, and sometimes hot cloths and poultices give great relief.

Of all internal remedies, there is but one of great value, namely, opium. This

in large doses (a grain—grm. 0.05—of extract of opium every hour) almost always proves beneficial. It moderates both the pain and the vomiting or eructations; and also, by diminishing the peristaltic movements of the intestine, opium contributes in another way to assuage the suffering and possibly to limit the spread of the inflammation. Experience shows that almost all patients bear even very large doses of opium remarkably well in peritonitis. Perhaps this is because the drug is only slowly absorbed. To substitute injections of morphine for the opium is wise only in cases where we wish to produce narcosis as rapidly as possible, or where the vomiting does not prove amenable to the ordinary treatment.

Sometimes particular symptoms demand special attention. For vomiting we may employ, besides opium, bits of ice, or small quantities of "sherbet." If tympanites is excessive, we may try to remove some of the gas through a rectal tube passed as high up as possible. Many physicians also puncture the distended intestinal coils with a fine trocar. Collapse and cardiac failure require the exhibition of stimulants, such as champagne or other alcoholic liquors, or doses of ether or camphor given subcutaneously. It is generally very difficult to nourish the patient. As a rule, small quantities of ice-cold milk are the best of anything, as food.

The treatment of circumscribed peritonitis should conform in general to the above indications. In suitable cases operative interference may be of great value; but upon this point we refer to works on surgery.

## CHAPTER II.

### CHRONIC PERITONITIS. TUBERCULAR PERITONITIS.

**Etiology.**—Chronic peritonitis, not tubercular, is a rather rare disease. It is found most frequently in post-mortem examinations of patients who have had for a long while ascites due to venous stasis—for example, in chronic cardiac or hepatic cases. The chronic peritonitis, however, is not, as a rule, the direct result of the passive hyperæmia in such cases, but is, as already hinted, due to the puncturing of the abdomen during life for the removal of the ascitic fluid. Exceptionally, a chronic peritonitis occurs as a sequel to some severe intestinal disorder, such as ulceration. Thus, chronic peritonitis is sometimes observed to follow typhoid fever.

Chronic peritonitis may furthermore be the result of an acute peritonitis. The latter seldom terminates in this way, but still it may, when rather mild and not quickly fatal. The encapsulated exudations of peritonitis usually persist a long while, as was implied in the preceding chapter.

In a few instances we can find no satisfactory cause for chronic peritonitis. It is sometimes ascribed to an injury. Alcoholic excesses are also said to predispose to the disease. Many of the apparently spontaneous cases, however, finally turn out to be tubercular.

The tubercular is the most frequent form of chronic peritonitis. It is often merely a part of the tuberculosis of serous membranes in general (*vide* pages 291 and 327), of which mention has been already repeatedly made. In these cases it is usually due to a conveyance of the process from the pleura through the diaphragm. Another way in which tubercular peritonitis may arise is by infection from neighboring tubercular organs. Tubercular intestinal ulcers are among the chief causes of this kind, the ulcer extending to the peritoneum; or the peritonitis may be excited by tubercular retroperitoneal or mesenteric lymph-glands. In women a

tubercular peritonitis may be developed in consequence of tuberculous of the genital organs. A tuberculosis of the uterus sometimes affects the Fallopian tubes by direct extension, and thence the virus enters the abdominal cavity and excites its specific inflammation. In conclusion, we have to mention that, in general miliary tuberculosis, the peritoneum also may be the seat of numerous tubercles, although these do not as a rule give rise to important symptoms.

**Pathology.**—After well-marked cases of chronic peritonitis, the peritoneum is usually found to be considerably thickened. The intestinal coils are joined to one another and to the neighboring organs by numerous and extensive adhesions. It is often a hard matter to disentangle the confused mass into which the intestines have been rolled. Sometimes the liver and spleen are covered by firm, tough capsules. The omentum and mesentery are much shrunk; hence the name *peritonitis deformans*. The mesentery may indeed be transformed into a single thick cord. As a rule, there is little liquid effusion, and perhaps none. In simple chronic peritonitis, such fluid as may be present is usually a cloudy serum, pus being seldom seen.

The milder forms of simple chronic peritonitis occur oftenest, as we have said, in cases of ascites due to venous stasis, after repeated tapings. It is frequently possible to detect the points where the trocar has pierced the internal layer of the abdominal wall, by adhesions, minute hemorrhages, or other lesions. The false membranes which exist in these cases are often very numerous, but they are usually not dense and are easily separable. The serous liquid found in the abdominal cavity is partly a transudation, but contains clumps of fibrine in more or less abundance. In rare instances a peculiar form of chronic peritonitis has been observed as a sequel to punctures for ascites, called by Friedreich "chronic hæmorrhagic peritonitis with hæmatoma." In it almost the entire peritoneum is covered by a newly formed membrane permeated with large ecchymoses.

Tubercular disease of the peritoneum may be divided into two forms: tuberculosis of the peritoneum, which may be acute or chronic; and tubercular peritonitis, which is usually chronic. In tuberculosis the peritoneum is covered with numerous tubercular nodules, varying in size from a millet-seed up to a pea: but there is not much coincident inflammatory change. In genuine tubercular peritonitis, on the other hand, the inflammatory changes above described are well marked, while sometimes it requires a microscopic examination to demonstrate the tubercular nature of the inflammation, by the detection of tubercles and cheesy degeneration in the newly formed tissue. Tubercular peritonitis is usually rather chronic, so that the adhesions are numerous and strong. The amount of liquid effusion varies, being sometimes considerable and sometimes scanty. Just as in tubercular pleurisy, it is not rare for the exudation to be bloody. Tubercular peritonitis is quite often accompanied by hepatic cirrhosis (*q. v.*).

**Clinical History.—Diagnosis.**—If an acute peritonitis becomes chronic, the violent symptoms gradually abate, while another group of symptoms takes their place. In other cases the chronic disease develops gradually and insidiously.

The sensitiveness of the abdomen is never so extreme as in the acute inflammation. Sometimes, to be sure, the patient complains of dull pains and a sense of abdominal oppression, but quite often the pain is either constantly or at times insignificant. On physical examination, we usually find moderate distention of the abdomen. Frequently this is not perfectly uniform, certain coils of intestine being especially prominent. Occasionally there is no abdominal distention whatever, the belly is flat or concave, and the walls are tense and unyielding.

In many instances palpation furnishes very characteristic signs: for sometimes the thickening of the omentum and the numerous fibrous inter-intestinal bands above described can be felt through the abdominal walls as peculiarly resistant

masses or uneven prominences. Indeed, if the omentum is rolled up, it may closely simulate a new growth. Not infrequently, particularly in tubercular peritonitis, the liver is enlarged so that its lower edge can be felt. But in other cases of chronic peritonitis there are no changes discoverable by palpation: or they may be concealed by an effusion or by the tenseness of the abdominal walls. A large exudation can be demonstrated by the great distention, or by its causing fluctuation, or by the signs yielded on percussion. In general, uncomplicated cases do not give rise to great accumulations of fluid. Such accumulations are almost invariably present when tubercular peritonitis and cirrhosis of the liver are combined; and here there are usually also passive congestion and enlargement of the spleen. It has been already stated that the distortions and flexions which the intestines may undergo in chronic peritonitis may result in obstruction. In the same way the duodenum or the ductus choledochus may be so occluded as to occasion persistent jaundice.

The objective signs of both the simple and tubercular forms of chronic peritonitis have been embraced in one description, because the abdominal signs of the two are identical. To differentiate between them, other factors must be considered. We regard the patient's constitution and general appearance, and inquire into his family history, or discover if there are other ætiological factors, such as previous tubercular disease. A careful thoracic examination is extremely important. If we find the signs of coincident pulmonary tuberculosis, and particularly of pleurisy, then it is almost indubitable that the peritonitis is tubercular. The character of the exudation is also of some importance, for if hæmorrhagic, as already stated, the peritonitis is probably tubercular. Tubercle bacilli are not usually present in the exudation of tubercular peritonitis.

To diagnosticate simple tuberculosis of the peritoneum, when not attended by marked inflammatory changes, is generally a difficult matter. Often it is absolutely impossible. Frequently there is no abdominal pain or tenderness whatever. The abdomen is usually but moderately distended, as a result of the effusion present.

Particular notice should be given to the chronic peritonitis of children. The occurrence of ascites in children between the ages of two and ten years has been observed repeatedly, both by other authors and by ourselves. The ascites, which may be quite considerable, can not be traced to any cause, and after a few months completely disappears. The child during this time is usually rather pale and languid, but not much emaciated, nor does he suffer great local discomfort. Since the cases often recover, their pathological anatomy remains obscure. Probably they are a mild form of simple chronic peritonitis. Still, of course, there may be other causes for the ascites, such as hereditary syphilitic disease of the liver.

In children, tubercular peritonitis plays an important part in general tuberculosis of the abdominal organs, a condition known as *tabes mesenterica*. In these cases the tuberculosis probably originates, as we have already said, in the intestine, so that usually we find the intestine, peritoneum, liver, and abdominal lymph-glands all simultaneously involved. The clinical symptoms are often mainly due to the peritonitis. The abdomen is distended and painful, and there is an effusion. Often there is also obstinate diarrhoea, as a result of tubercular intestinal ulcers, with persistent fever of an intermittent character, emaciation, and anæmia. The tubercular process may eventually involve the lungs, pleura, meninges, and other organs, or it may never extend beyond the abdomen.

As to the course of chronic peritonitis we have little to say. The simple chronic peritonitis may terminate in recovery, although on account of other co-existing lesions this event is rare, except in the special form which children

present. Many cases of tubercular peritonitis prove fatal in a few months or weeks. In some instances, however, chronic tubercular peritonitis has a favorable issue, or at least there is very great abatement of all symptoms. This is particularly apt to be the case in what is called primary tuberculosis of the serous membranes in general (*vide supra*). If, in this disease, there is no simultaneous tuberculosis of the lungs, intestines, or other organs, then the final reabsorption of the exudation is possible, just as in tubercular pleurisy. It must be confessed that often the recovery is not permanent, for the tubercles may appear later in some other part of the body.

**Treatment.**—The means by which we can exercise a favorable influence upon the course of chronic peritonitis are scanty. Attention to nourishment and hygienic surroundings is very important; but, beyond this, treatment is mainly symptomatic. The chief local applications are poultices or fomentations, perseveringly employed. There is seldom such persistent and severe pain as to demand opiates, but they may be required for the diarrhoea which is apt to occur. Or, on the other hand, enemata and mild laxatives may be indicated. Among special remedies, the preparations of iodine should be mentioned; iodide of potassium and syrup of the iodide of iron sometimes are of apparent benefit. Arsenic may also be tried. Iron and syrup of the iodide of iron are also employed in the chronic peritonitis of children.

[Of recent years laparotomy has been repeatedly practiced in tubercular peritonitis, and has been held by some to be distinctly curative. In the opinion of the editor, what surgery has done for us in this affection is rather to demonstrate the curability of many cases than to work their cure. Formerly, if the diagnosis of tubercular peritonitis was made and the patient recovered, the very fact of recovery was held to invalidate the diagnosis. But the surgeon's knife has laid bare the miliary tubercles to the eye, given an exit to the serous exudation, and recovery has ensued. But we see other cases get well after simple tapping, and we see still others which present just as good a clinical picture of the affection and recover without interference of any kind. Such recovery may be temporary, tuberculosis breaking out afresh in the peritoneum or elsewhere, or it may be permanent. If, in spite of rest and appropriate general treatment, considerable effusion persists, aspiration or siphonage should be practiced. Laparotomy should probably be reserved for those rather rare cases which seem to be rapidly getting worse, and those in which the fluid reaccumulates after one or more tapplings.]

In expressing the belief that tubercular peritonitis recovers, the editor does not lose sight of the fact that multiple fibrous nodules occur disseminated over the peritoneum, indistinguishable by the unaided eye from tubercles.]

### CHAPTER III.

#### ASCITES.

(*Hydroperitoneum.*)

THE name ascites is given to a collection of transuded serum in the abdominal cavity, due to venous stasis. The peritoneal veins belong to the portal system, so that among the diseases which lead to ascites those which impede the portal circulation are chief. As we shall see in the next section, ascites is, therefore, of frequent occurrence in cirrhosis of the liver, syphilitic disease of the liver, compression of the portal vein by tumors, thrombosis of the portal vein, and similar

disorders. Ascites is also frequently present as one of the dropsical symptoms in general circulatory disturbances, such as cardiac disease or pulmonary emphysema, and in the various acute and chronic renal affections.

The clinical significance of ascites is due partly to the local discomfort occasioned by the presence of any considerable amount of fluid within the abdominal cavity. Small quantities of serum are often unnoticed by the patient; but, where many quarts (fifteen to twenty, or even more) of transudation exist, the abdominal walls become greatly distended, and the patient has a very troublesome feeling of pressure, weight, and tension. What is of still greater importance is the crowding upward of the diaphragm. Respiration is thereby not a little impeded. If the ascites is great, the lower lobes of the lungs are so compressed that a considerable degree of atelectasis is produced.

To demonstrate ascites by physical examination is possible only when a considerable accumulation exists. Then the belly is prominent, its walls are tense and shining, and, the base of the thorax being gradually distended by the pressure of the liquid, the lower part of the thorax seems much broader than the upper. Distended veins are usually visible through the skin of the abdomen, like blue lines, here and there. As soon as the abdominal tension has attained a certain degree, fluctuation can be perceived, by laying both hands upon the abdomen and imparting gentle but quick impulses to the fluid through the walls. Percussion gives a dull sound everywhere that the fluid is in contact with the abdominal walls. Gravity, of course, leads the liquid to occupy the dependent parts. In the dorsal decubitus, and when the transudation is of medium amount, the dullness is bounded in the central and upper parts of the abdomen from a region of tympanitic resonance by a line concave toward the head of the patient. The surface of the liquid being horizontal, of course the dullness reaches nearer to the thorax along the sides of the abdomen than in the central line. We would add, that where the layer of ascitic fluid is thin we can obtain dullness only by light, superficial percussion. If the pleximeter or finger is pressed deeply in, the fluid is crowded to one side, and we get a tympanitic sound from the underlying coils of intestine. A factor of great diagnostic value is the change of dullness on change of position of the patient. If he lies upon one side, the fluid seeks the dependent portions of the cavity, and gives rise to extensive dullness there, while the opposite side now yields a tympanitic resonance. Or, if he changes to the other side, it in turn becomes dull, and the side previously dull becomes tympanitic. Similar differences are found between the results of percussion in a horizontal and in a sitting posture. It is only when the accumulation is very abundant that there is dullness over the entire abdomen.

The signs mentioned enable us in most cases to make a diagnosis of ascites with ease and certainty. It is, indeed, not always easy to distinguish a transudation of serum from the exudation of chronic peritonitis, for, of course, either sort of fluid would yield the same physical signs. Only, the change in the area of dullness consequent upon a change of position is less pronounced in case of an exudation, because the peritonitic adhesions impede the movements of the fluid; and we have, besides, all the other symptoms to guide us; there may be pain, or thickenings of the peritoneum discoverable on palpation, or signs of tuberculosis; or, on the other hand, there may be some cardiac or hepatic disease, which would render ascites probable. If the fluid is drawn off, its character will sometimes aid us in diagnosis. Ascites yields pure serum, containing almost no morphological constituents. Its specific gravity is usually less than that of a peritonitic exudation, because it contains less albumen. We may say that the specific gravity of the fluid found in peritonitis is generally above 1018, and that of ascites about 1012, or even lower. Hemorrhagic ascites sometimes occurs in

anæmic patients who are suffering from marked portal obstruction, as we have ourselves seen, for example, in hepatic syphilis.

There may be equal difficulty in the exclusion of ovarian cysts, particularly since the cysts are sometimes so large as to fill the whole abdominal cavity. We must first map out accurately the dullness on percussion, and also see if it varies with changes of position. In cases of ovarian tumor, change of position does not make much difference. The resonance on percussion of the deepest and most dependent portions of the abdomen may be misleading, in this way, that even in ascites a narrow zone here may be tympanitic. This should be remembered. Thus, just above the symphysis, there is sometimes a tympanitic resonance in ascites which might readily be mistaken for a proof of the existence of an ovarian tumor. The explanation is that in the places indicated a coil of intestine with a short mesenteric attachment may remain in contact with the abdominal wall in spite of ascitic accumulations. Further aid in the differential diagnosis is to be obtained from the history of the case (place where the swelling began), from a consideration of possible causative diseases, and from a vaginal examination. In ascites the uterus is freely movable, while in case of ovarian tumors it is often bound down by adhesions. Further particulars may be sought in books on gynaecology.

The treatment of ascites, of course, depends largely upon the disease of which it is a symptom. As to the symptomatic treatment of ascites itself, we will confine ourselves to a few words about tapping. This operation is indicated when the local disturbances caused by the ascites are great; that is, if there is an unbearable sensation of pressure and tension, and, above all, if the crowding up of the diaphragm causes much dyspnoea. The instrument to be used is a common trocar of medium size. Usually the patient is tapped lying on his side in bed, at the most dependent point in the lateral portion of the abdominal walls; but it is also a good way to make the puncture in the median line, about half-way between the umbilicus and the pubes, with the patient in a chair. The operation is easy, and almost free from danger. We may allow large amounts of liquid (five or ten quarts, or more) to flow slowly away at one tapping. Over the puncture we put a piece of sticking plaster, or, if great caution is to be exercised, an antiseptic bandage. Often the fluid trickles out through the opening, because the abdominal walls have lost their elasticity on account of the persistent distention. We may then employ a "circumvolved suture" to close it. After tapping, the laxness of the walls is favorable to palpation of the abdominal organs.

Inasmuch as tapping does not remove the cause, there is in most cases a very rapid reaccumulation of fluid. Thus the system is deprived of much albumen, and nutrition is impaired, so that not infrequently the operation is followed by decided loss of strength. Therefore, we should not tap in ascites, as a rule, unless the indications for the operation are urgent.

[Before puncture the precaution should always be observed to see that the bladder is empty.

If, as is very frequently the case, the fluid continues to drain away through the puncture after the trocar is withdrawn, good rather than harm results, provided the danger of irritation of the skin and of bed-sores is kept in mind and guarded against, and an instrument of moderate size is used.

Flint advocates early and repeated tapplings if the fluid causes discomfort and does not yield to diuretics or cathartics. The pressure is removed in a measure from the abdominal and thoracic organs, and nutrition is thus promoted. The fluid is likely to return, but does not always do so, or may do so only slowly. He reports cases in which, after repeated removal, the fluid ceased to return and the

patient remained apparently well. The result must depend, of course, chiefly on the underlying cause, which is sometimes very obscure.

In cases of cirrhosis the same principles govern Flint's treatment.]

#### CHAPTER IV.

#### CANCER OF THE PERITONEUM.

CARCINOMA is the only new growth of any practical importance to which the peritoneum is liable. Primary endothelial cancer, analogous to the growth which attacks the pleura, is very rare. Cancerous growths here are usually secondary to cancer of the stomach, intestine, pancreas, liver, or some other organ. Often the secondary nodules are numerous, and almost as small as peas, presenting what is called miliary carcinosis of the peritoneum. Separate nodules of larger size are less frequent. These may be found in the omentum, in Douglas's pouch, around the navel, or in other situations. Colloid cancer attains the most diffuse and extensive development of any variety. The retroperitoneal lymph-glands may also present at the same time large cancerous growths. Often the development of cancer in the peritoneum is attended with pronounced inflammatory disturbances—that is, we have a cancerous peritonitis.

The symptoms of peritoneal cancer resemble in many points those of chronic tubercular peritonitis. Simple miliary carcinosis may be very insidious and give rise to no special symptoms, so that it often is unsuspected. In many cases a moderate amount of fluid collects in the abdomen, and this, if we are aware of the existence of a primary cancerous growth, may lead us to surmise a secondary peritoneal carcinosis. The symptoms are much more pronounced if there is cancerous peritonitis. In that case there is usually very severe pain, marked abdominal distention, and constipation. We may sometimes feel the larger nodules in the omentum or upon the inner surface of the anterior wall of the abdomen, or even those in the lowest part of the abdomen, by palpation through the vagina. If the exuded fluid be drawn off, it is sometimes merely serous, but it may be hemorrhagic. When the new growth has been diffuse, and particularly in case of colloid cancer, the exudation has repeatedly been found to present a milky opacity. Sometimes this fluid also has been tinged with blood. The opacity is due to fat, from fatty-degenerated and disintegrated cancer cells. Occasionally the microscope reveals characteristic cancerous elements in the fluid.

The diagnosis can not be made with any positiveness unless, as a sequel to a primary cancerous growth already demonstrated, we observe the evident tokens of peritoneal disturbance, such as free fluid and pain. Other points are the patient's age, cancerous cachexia, and secondary glandular enlargements, particularly in the groins.

Treatment must be confined to efforts at mitigation of the suffering. Warm applications, morphine, and supporting measures are chiefly employed.

---

## SECTION VII.

*DISEASES OF THE LIVER, BILE-DUCTS, AND PORTAL VEIN.*

## CHAPTER I.

## CATARRHAL JAUNDICE.

*(Icterus catarrhalis. Gastro-duodenal Catarrh with Jaundice.)*

**Ætiology.**—When discussing intestinal catarrh, we mentioned that inflammation of the duodenum may invade the secretory ducts of the liver, and, above all, the ductus choledochus communis. This complication would be of little clinical importance did it not in many instances prevent the flow of bile into the intestine. Such an obstruction at once gives pathological interest to a catarrh of the bile-ducts, because it entails a series of very important clinical symptoms. In this case the cause of the biliary stasis is purely mechanical, and any closure of the hepatic ducts, however produced, gives rise to identical symptoms, which vary, if at all, only in their duration and intensity. Catarrhal jaundice is therefore only one form, though the most frequent form, of what is called hepatogenous jaundice. Accordingly, we will in this chapter describe in detail the general phenomena common to all cases of hepatogenous jaundice, that we may avoid needless repetitions hereafter.

The causes which lead to a gastro-duodenal catarrh, with consequent jaundice, may be the same which produce ordinary gastric catarrh—such as errors in diet. But we must emphasize the fact that we see catarrhal jaundice so often without any striking cause, as strongly to suggest the thought of some specific lesion, some special pathogenic agent. The precise facts are indeed yet to be learned; still it has been often observed that at many times (particularly in spring and autumn) it assumes epidemic proportions. The infectious nature of the jaundice is still more probable in those cases where the disease is decidedly endemic. In barracks, prisons, and single houses quite important endemics of jaundice have been seen, the only explanation for which could be found in assuming the existence of some local source of infection. In a few cases, epidemics of catarrhal jaundice have followed revaccination, compelling one to think that possibly the pathogenic agent was transferred by inoculation. Patients themselves not infrequently refer to taking cold, or to mental emotion (particularly anger), as circumstances promoting the disease.

Another cause is the rather frequent occurrence of duodenal catarrh as a result of passive congestion. This is seldom very intense. It is especially frequent in heart disease. Again, the slight jaundice quite often seen in the course of many acute diseases, and of lobar pneumonia in particular, must be ascribed to catarrh.

**Pathology.**—As in catarrhal affections of most other mucous membranes, the post-mortem signs of catarrh of the bile-ducts are not always striking, for the swelling and injection subside considerably after death. The usual method of testing the patency of the common duct is by pressing upon the gall-bladder to see if its contents can be squeezed out into the intestinal canal. If a catarrh has closed the common duct, the bile is not discharged at once. A firmer pressure drives out from the opening of the duct a plug of tough, white mucus, upon which the bile follows; but such a plug is not present in every case, by any means, for even a simple swelling of the catarrhal membrane suffices to obstruct the flow of bile.

If the biliary passages are slit open, the common duct is found more or less

filled with tough, white mucus. Usually the portion which lies in the intestinal wall, the so-called intestinal portion, is most affected. Behind the occluded part the ducts are distended, if the biliary retention has been chronic. This distention may involve even the smallest ducts, which lie in the liver itself. As a consequence, the liver is somewhat enlarged and has a diffuse bilious tinge. If the obstruction persists for a long while, which is very exceptional in simple catarrhal jaundice, a portion of the hepatic cells are destroyed by the pernicious influence of the retained secretion. The lost parenchyma is replaced by new-formed connective tissue. For further particulars, see the chapter on biliary cirrhosis.

**Clinical History.**—Inasmuch as catarrh of the ductus communis is almost always consequent upon a gastro-duodenal catarrh, the first symptoms are usually referable to the latter disease. It is indeed seldom that the attack begins with marked gastric disturbances, like violent vomiting and gastralgia, but almost invariably the jaundice is preceded for a variable period by indisposition, as shown by malaise, languor, anorexia, a bad taste in the mouth, nausea, gastric oppression, eructations, and sometimes temporary vomiting. Then comes the first evidence that the catarrh has invaded the common duct, in a jaundiced hue of the skin and of the visible mucous membranes. In many cases, however, the initiatory gastric symptoms are almost wholly absent, so that the disease begins immediately with the appearance of the jaundice.

The pressure in the secretory ducts of the liver is extremely low, so that even the catarrhal swelling of the mucous membrane and the collection of viscid mucus in the common duct suffice to impede in a marked degree the further outflow of bile into the intestinal canal. As a rule, however, the retention of bile is not complete, or, if so, only for a time. Still a considerable amount of bile collects, and distends even the intra-hepatic ducts. As soon as this stasis has reached a certain point, the stagnant bile is absorbed by the hepatic lymph-vessels. Thus the bile and all its constituents are poured into the blood by way of the thoracic duct and carried to all parts of the body.

No more than a few days need elapse before the bile-pigments are absorbed into the tissues, and give rise to the evident yellow color of the skin and mucous passages which we call jaundice. Usually the yellowness of the conjunctiva is the first thing to attract attention. Later the entire skin becomes yellow, and the same color is plainly visible in the mucous membrane of the mouth and throat, especially after we have produced temporary anemia by pressure, as in the lips. Of course, the internal organs, which we can not see, are likewise stained. Any abnormal collection of liquid will also have a marked yellow color. The cornea, the peripheral nerves, and the cartilages alone escape unstained. In other parts we may not only find this diffuse impregnation with the biliary pigments, but even solid granules of the latter.

A jaundiced patient often presents other indications of the presence of biliary coloring matter than the color of his skin. If the jaundice is at all chronic, there is almost invariably an itching of the skin, which may be very troublesome. It may be so bad at night as to disturb sleep. The scratching thus induced often causes numerous excoriations and fissures, which may even occasion quite large furuncles. Urticaria is also sometimes observed. A peculiar disease of the skin, which has been chiefly described by English authors in connection with jaundice, is called *xanthelasma*. It presents bright-yellow spots, usually somewhat elevated, which are found mainly on the eyelids, though also on other parts of the body.

The remaining symptoms of hepatogenous jaundice may be divided into two groups. The first group comprise the symptoms excited by the presence of the biliary constituents, and particularly of the biliary acids, in the blood, while the second group are due to the lack of bile in the intestinal canal.

We have seen that, when the biliary outlets are occluded or narrowed, the constituents of the bile are absorbed by the lymphatics. We have already learned in part what becomes of the bile-pigments thus conveyed into the blood-vessels. The presence of the bile-acids in the blood is also of considerable clinical importance. Physiology has shown that these acids possess certain poisonous properties, and, among others, the power to destroy red blood-corpuscles. But in reality few if any blood-corpuscles are destroyed by the bile-acids in the blood, because they are too much diluted, and, besides, seem in large part to be quickly decomposed after absorption. These acids do really, however, excite certain nervous centres in a way to give rise to decided clinical symptoms. The most frequent effect is that produced by the cholate of sodium upon the cardiac ganglia, or possibly also upon the center for the vagus, and it is evinced by a slowing of the pulse. This is an almost invariable phenomenon, provided there be no fever or other complication, and is seen not only in simple catarrhal jaundice but in all cases of hepatogenous icterus. The pulse-rate is from 64 to 50, or even less. Slight irregularity in the heart's action is not infrequent. There are certain other nervous disturbances often seen in jaundice and referable to the presence in the blood of biliary constituents, and in particular of biliary acids. Sometimes there is a striking languor and muscular weakness, or headache, or the patient is "out of sorts." Grave nervous symptoms, sometimes seen in jaundice and grouped under the name of *cholæmia*, are discussed in another chapter. It also deserves a brief mention here that many cases with marked jaundice have a noticeable tendency to bleeding—that is, a sort of "hæmorrhagic diathesis." Hæmorrhages into the skin and in the viscera are quite often seen, and also epistaxis and analogous occurrences.

We now come to the second group of symptoms, which result from lack of bile in the intestinal canal. It will be easy to understand these if we briefly review the physiological functions assigned to the bile which is poured into the alimentary canal. Bile plays an important part in the digestion of fat, emulsifying it, and promoting its absorption into the chyle-ducts. Now, in hepatogenous icterus this work remains undone, as is shown by the fatty stools. From time immemorial the white clay-colored stools of jaundice have been well known, and are employed as the best measure of the completeness of biliary retention. The light color of the stools is partly due to the lack of biliary pigment, for it is that chiefly which imparts to normal *fæces* their dark-brown color; but the characteristic white clay color is due exclusively to the presence of undigested fat in large amounts. We have ourselves performed the experiment of putting a patient with extreme hepatogenous icterus upon a diet containing as little fat as possible, and have found that the stools then became light brown, and not at all like clay. Upon microscopic examination of the *fæces* in jaundice, sheaf-like aggregations of crystals are not infrequently observed. These were formerly supposed to be tyrosine, but Oesterlein has shown them to be in reality magnesia-soap.

The retention of bile has some further effects besides retarding the digestion of fat. Bile possesses decided antiseptic properties, and thus, to a certain extent, protects the contents of the *primæ viæ* from putrefaction. In hepatogenous jaundice, therefore, the processes of decay are abnormally active; the *fæces* are unusually offensive, and there is an excessive generation of gas, often leading to flatulence and tympanites. The bile also undoubtedly stimulates peristalsis, and so in jaundice there is often constipation.

One important function of the bile remains to be considered—namely, that by precipitating pepsine it terminates peptic digestive action. Kühn has shown how necessary this is to the normal processes, because pepsine will destroy pan-

creatine, and therefore interferes with pancreatic digestion. Hence we are justified in assuming that in well-marked jaundice the digestive action of the pancreatic juice on fat and albumen is probably disturbed, even though the pancreas itself secretes normally. Often, and in catarrhal jaundice probably as a rule, the pancreatic duct is obstructed as well as the biliary, so that not only the bile, but also the pancreatic juice is retained. Just how far the digestive disturbances are to be ascribed to the lack of each of these secretions we are of course unable to determine.

We must now inquire what becomes of the absorbed bile. As to the biliary acids, we have already said that they probably undergo decomposition. Of the other constituents, including the taurine and cholesterine and the pigmentary matters, we know the fate of the last-named only—that is, we have learned how Nature seeks to rid herself of this foreign substance. As soon as the amount of bile-pigment in the blood and tissues becomes considerable, excretory efforts are made, in which the kidneys take the chief share. Certain changes take place in the urine almost simultaneously with the first appearance of a jaundiced hue in the skin; and these changes are due to the urine containing excreted biliary coloring matter.

The urine of jaundice is generally recognizable from its color, which is a dark brown, like beer. The foam caused by shaking it is not white, but distinctly yellow. A bit of white filter-paper dipped in the urine is stained yellow. If the urine is mixed with chloroform in a test-tube, the chloroform dissolves the pigment, and, on being allowed to collect at the bottom of the tube, displays a deep-yellow color. This is known as the "chloroform test." Another reaction which usually gives a satisfactory result, but not always, is Gmelin's. If urine containing bile-pigment is slowly poured down the sides of a test-tube containing some fuming nitric acid, the zone between these two liquids exhibits a fine play of colors. The effect of the acid upon the biliary pigment is to produce a number of colored rings, the highest and most characteristic of which is green; next comes blue, then violet and red. Gmelin's test often shows very prettily if one filters the urine and then adds a drop of nitric acid to what remains upon the moist filter-paper. The characteristic colored rings form around this drop.

The biliary acids also may be detected in the urine of jaundice; but the process is somewhat tedious, and the knowledge gained is of no practical importance.

The urine very often contains morphological elements which are characteristic. Nothnagel was the first to describe minutely the icteric casts—that is, hyaline casts which usually have a yellow tinge and quite often are completely covered with dark-yellow granules. The urine may contain a little albumen also, but this is not constant.

[The presence or absence of albumen depends largely on the amount of the biliary constituents and on the length of time they continue in action on the kidneys; their effect on these organs is more or less that of an irritant.]

The sweat-glands also take part in the excretion of bile-pigment. The latter can be demonstrated in the perspiration of jaundiced persons, as well as in their urine. Not infrequently the patient's linen is colored yellow by the sweat. On the other hand, no bile-pigment is found in the tears, saliva, gastric juice, or secretions other than those mentioned.

Having now considered the phenomena common to all cases of hepatogenous icterus alike, we revert to the subject of simple catarrhal jaundice. The prodromal gastric symptoms usually last a few days, more rarely a week or two, when the skin becomes evidently jaundiced and the other results of the icterus are also seen. The urine grows dark with biliary pigment, the stools become light-colored and more or less clay-colored. The nervous system is not usually seriously de-

ranged, but still most patients feel very languid, and have anorexia and a tendency to constipation. The pulse becomes somewhat slower than normal, and sometimes the temperature also is subnormal, say 97° or 98° (36°-36.5° C.).

In most cases the physical examination of the liver is of interest, the organ being, as already mentioned, enlarged from the retained bile. Accordingly the lower boundary of hepatic dullness usually extends two or three finger-breadths below the edge of the ribs, and not infrequently the lower margin of the organ can be plainly felt. Often the gall-bladder is so distended, both by bile and by the mucus which it itself secretes, that it projects from under the edge of the liver. In such cases, as Gerhardt tells us, we may sometimes make out by percussion a convexity in the lower line of hepatic dullness, which corresponds to the gall-bladder. If the abdominal walls are lax, we may even feel the distended viscus. As a rule, there is not much distress in the hepatic region, although now and then there is a certain sensation of pressure or tension.

The symptoms depicted seldom last longer than a few weeks. Usually a patient who takes proper care of himself begins to feel better in even less time. The urine grows lighter colored, the stools darker, and the pulse more rapid. The yellow color of the skin often remains visible for quite a while, although gradually diminishing, even after the patient feels perfectly well; but at last the jaundice disappears also and recovery is complete. Relapses are indeed possible, particularly after errors in diet; but they are rare.

The termination of catarrhal jaundice is, therefore, almost invariably favorable. The entire course of the disease occupies about three to six weeks, rarely a longer period. It is a very exceptional occurrence, but one which we must always think of as possible, for this apparently mild and secure condition to be suddenly merged into the grave, pernicious variety of jaundice. (See the chapter on acute yellow atrophy of the liver and pernicious jaundice.)

**Diagnosis.**—Catarrhal jaundice is usually easily diagnosticated. The diagnosis is made chiefly from the course of the disease—the development of jaundice, preceded by gastric symptoms, in a previously healthy person, and generally in a youthful individual. It is very important to exclude other conditions which might occasion jaundice. We must consider, therefore, whether the history of the case suggests the presence of gall-stones (hepatic colic), and be vigilant in our physical examination to detect a possible cirrhosis or new growth. In the case of elderly patients, particularly, it is not rare for what was at first regarded as an attack of ordinary catarrhal jaundice eventually to disclose itself as a grave chronic disease. We should not make a diagnosis of catarrhal jaundice until we have carefully weighed all the rational and objective signs.

**Treatment.**—Most cases of catarrhal jaundice terminate favorably and require no active treatment. Rest and prudence are indicated, and the diet should be carefully regulated, that the gastro-duodenal catarrh may not be aggravated. Fat must not be eaten, for, as we have seen, it is not assimilated, and only excites abnormal processes of decomposition in the intestinal canal. Lean meat, bread, soups, if not too rich, vegetables, preserves, and lemonade or tamarind-water are allowable.

We should also employ internal remedies to mitigate the catarrh. The various stomachic tonics are frequently prescribed. Rhubarb is a favorite drug. A very good medicine is Carlsbad water, or the artificial Carlsbad salts, of which latter the dose is half a teaspoonful to a teaspoonful, in a tumbler of warm water, before breakfast. The alkalies not only exert a direct beneficial influence upon the gastric mucous membrane, but are also useful as laxatives. More obstinate constipation may call for castor-oil, calomel, or rhubarb.

Lately much enthusiasm has been displayed about the treatment of catarrhal

jaundice by large enemata of cold water. The injections are said to overcome the biliary retention by exciting peristalsis, and possibly by also promoting the secretion of bile. Once a day a quart or two of water, at 60° to 70° (12°-18° R.), is injected, and is retained as long as possible. The good effect is said to be observable in a few days, both in the general condition of the patient and in the diminished amount of bile-pigment in the urine, as well as the darker color of the stools.

The effort has also been made to empty the gall-bladder by manipulation. Gerhardt states that sometimes the distended viscus can not only be felt through the abdominal walls (*vide supra*), but it can be so firmly compressed as to squeeze its contents into the duodenum. Sometimes the obstruction is said to yield suddenly, as if a plug were driven out. This method has not been universally adopted. It seems applicable only in a limited number of cases, and is probably not free from danger. Several authorities have recommended external faradization as a means to stimulate the gall-bladder to contract and discharge its contents. We believe that few will adopt the suggestion.

#### APPENDIX.

##### ACUTE FEBRILE JAUNDICE. WEIL'S DISEASE.

Within a few years an acute infectious disease has become known, which invariably causes jaundice and may therefore be properly described in this connection. It was first described by Weil, then by Fiedler and others.

The disease is most frequent in the months of summer. It attacks by preference young and middle-aged men. Fiedler was struck by the frequency with which butchers suffered from it. The symptoms usually begin suddenly. Extreme chilliness, fever, headache, and malaise are almost always present at the onset. Jaundice usually appears on the second day, and it may become severe. Its immediate cause is doubtless obstruction of bile, for the stools are colorless, and the urine contains an abundance of bile-pigment. The constitutional symptoms remain for several days quite severe. The patient complains of violent headache, wakefulness, and vertigo. Sometimes there is evident stupor or mild delirium. Upon physical examination we not infrequently notice herpes on the lips, besides the icterus. The tongue is coated. There is nothing unusual about the lungs or heart, except that the pulse is apt to be quite rapid. The abdomen is not particularly distended. The liver is often enlarged, but not always. An acute splenic tumor is very often, but not invariably, present. There is usually diarrhoea. Vomiting may occur. There is generally albuminuria; and not infrequently the existence of a nephritis is shown by the blood and casts found in the urine. A very characteristic symptom is the violent pain in the muscles, particularly in the calves, of which most patients complain.

With these symptoms the disease persists for from five to eight days, during which period the fever is often very considerable. Temperatures of 105°-106° 8' (40°-41° C.) are not rare. Then the fever falls by lysis, although seldom with perfect regularity. At the same time the other symptoms abate also, and convalescence ensues after an illness of ten to fourteen days in all. Many milder cases recover even sooner. An unfavorable termination seems to be quite exceptional.

It is highly probable that this perfectly specific disease, the most important symptoms of which are, as we have seen, jaundice, fever, swelling of the spleen, albuminuria, and pain in the muscles, is an acute infectious process; but we do not yet possess any precise information as to its aetiology.

The treatment must be purely symptomatic. In the beginning calomel is use-

ful. Later on, hydrochloric acid, rhubarb, and the like are prescribed. The headache is relieved by an ice-bag, the pain in the muscles by rubbing with chloroform liniment.

## CHAPTER II.

### BILIARY CALCULI.

(*Hepatic Colic. Cholelithiasis.*)

**Ætiology.**—Although gall-stones are of very frequent occurrence, we do not yet possess much information as to their causation. It is only possible to state a few factors which very probably promote their formation.

Biliary retention certainly acts in this way, both directly and by leading to an increased consistency and increased concentration of the bile. As a result, certain constituents which were before held in solution are thrown down. And yet this cause, however potent, can not be regarded as the only one. The chemical examination of gall-stones leads plainly to the conclusion that their formation must be preceded by certain abnormal chemical processes of decomposition and of transformation. We can not otherwise explain why the constituents of gall-stones should differ, as they do in many ways, from the matters which normal bile holds in solution. For example, the pigment in gall-stones is never found unchanged, but invariably exists in composition with lime. Now, normal bile contains only a trace of lime, so that long ago Frerichs suggested that the lime comes from the mucous membrane of the gall-bladder. It is an important fact that the cholesterine, and probably also a portion of the pigmentary matters, are held in solution in normal bile by the combination of sodium with the biliary acids which it contains. If this sodium salt were decomposed from any cause, the matters named would naturally be precipitated. The decomposition of the salts formed by the bile-acids is greatly promoted if the bile acquires an acid reaction: but of the circumstances in which this last-mentioned change occurs we do not yet have any accurate knowledge. Possibly fermentation may have something to do with it. The idea that often a clump of mucus forms the nucleus of a biliary concretion lacks chemical confirmation, for mucus is never found in the stones.

We have rather more knowledge as to predisposing causes than about the chemical processes involved in the formation of gall-stones.

Age seems to be an important factor. The great majority of patients are over forty. Gall-stones are much less frequent between twenty and forty years of age; and in children they are very rare, although they have been observed in the newborn. One reason why elderly people are so liable to this trouble is said to be the senile weakness of the muscular fibers of the gall-bladder. Thus stagnation and retention of bile are promoted. It has also been suggested that in old age the bile may contain an excessive amount of cholesterine and lime.

Sex also has a decided influence. All authors agree that gall-stones are more frequent in females than in males, the proportion being about three to two. An explanation of this fact has been sought in the sedentary life of women, and particularly in the mechanical effect of tight lacing, impeding the outflow of bile.

Much has been said about certain peculiarities of bodily temperament in relation to cholelithiasis. Obesity, gout, and chronic endarteritis are said to favor the formation of gall-stones. A like influence is ascribed to excessive indulgence in meat and fat, as well as to gluttony in general, and to lack of exercise; but the real importance of these various factors is not at all definitely determined.

Diseases of the liver and bile-ducts do undeniably promote cholelithiasis, for they interfere in many ways with the discharge of bile from the ducts and from the gall-bladder. Thus they may cause compression or obstruction of a duct, or may lead to degenerative changes in the tissues of the gall-bladder. The view is quite generally held, but is apparently incorrect, that even a simple chronic catarrh of the bile-ducts tends to cause gall-stones. Gall-stones and catarrh of the ducts are indeed often found to co-exist, but it is probable that the catarrh is not the cause, but the result, of the presence of gall-stones.

**Occurrence, and Chemical and Physical Properties of Gall-stones.**—The place where gall-stones are most frequently found is the gall-bladder. We may find in it any number, from one or two up to a hundred and more. The size varies from that of a grain of sand up to that of a hen's egg. The large stones may completely fill the gall-bladder; and sometimes the smaller stones are numerous enough to fill it also. The stones usually lie free in the bladder, although exceptionally they may be found adherent to its walls. Rarely the bladder presents a diverticulum, in which a stone has been formed. The lining membrane of the viscus often suffers such mechanical irritation from the stones as to present quite a severe catarrhal inflammation. Sometimes there is even a more or less extensive necrosis (*vide infra*).

Stones which are found in the larger bile-ducts were not formed in them, but have become wedged in them while on their way to the intestine. This condition is described as an impaction of gall-stones. Gall-stones are quite often found in the liver itself, and frequently in large numbers. These concretions may measure half a centimetre to a centimetre in diameter. In such cases the small intra-hepatic bile-ducts are usually a good deal widened; or occasionally they present niches in which the stones lie. As a rule, the hepatic parenchyma surrounding the stone is in a state of chronic or acute purulent inflammation (*vide infra*).

In form, gall-stones vary infinitely. The smallest are irregular masses, well described by the name of "gall-sand." The larger stones are more or less round, or oval, or polyhedral. The polyhedra are usually due to the mutual rubbing and pressure of a number of stones upon one another. In color, the stones vary according to the amount of pigment they contain, from almost black or dark brown to a lighter greenish or bright yellow shade. A fresh gall-stone always sinks in water; but when dry, gall-stones contain air and generally float. On cross-section, they are found to be either homogeneous or composed of layers. As a rule, there is a nucleus, darkly pigmented, which is surrounded by a lighter-colored envelope, itself either made up of concentric layers or evidently crystalline. Often the outermost layers are still distinguishable as peculiar darker and harder strata.

As to chemical composition, gall-stones are usually divided into several groups. By far the most frequent variety is made up of cholesterine and pigment mixed together in greatly varying proportions. The pigment is part of it in its natural state and part of it combined with lime. On the average, stones contain about seventy to eighty per cent. of cholesterine. Besides these two chief ingredients, most stones also contain lime and magnesium. In color, they are light or dark according to the smaller or greater proportion of coloring matter they contain. Less common are stones of pure cholesterine. These are usually found singly, are soft, and often are almost transparent. Most cholesterine stones have a nucleus of pigment and lime in combination. Pure pigmentary concretions are rare, and are generally small, like coarse sand. A still greater rarity is a stone made up entirely of lime. Such a stone is small and very hard.

It should also be added that just as is the case with renal calculi, an organic cementing substance can be detected by the microscope in gall-stones. This is in part itself calcified, in part it unites the separate crystals (Posner).

**Pathological and Clinical Consequences of Gall-Stones.**—Gall-stones may remain for a long while in the gall-bladder, and even in the liver, without causing the slightest unpleasant symptom. It is not at all unusual to find gall-stones unexpectedly at an autopsy.

In other cases, however, gall-stones occasion severe suffering, and sometimes even death. These grave phenomena may be due either to certain mechanical conditions, like impaction, or occlusion of the bile-ducts; or to secondary inflammation resulting from their presence. These two kinds of disturbance must now be discussed in detail.

Gall-stones not infrequently leave the place where they were formed. Stones formed in the liver are gradually driven onward by the current of the bile, and pass through the hepatic duct into the common duct and the intestine. The more numerous concretions formed within the gall-bladder also often change their location. What should make them move is not perfectly determined. Probably there are various factors; in the first place, contraction of the muscular coat of the gall-bladder; and then probably the weight of the stone; and the pressure of the diaphragm and the abdominal walls, as in breathing, defecation, and vomiting. When once a stone has entered the biliary passages, we must regard the secretion behind it as the chief propulsive power; for neither the cystic nor the common duct possesses muscular fibers.

Small calculi may effect their escape without exciting any attention; but the passage of larger ones produces a very characteristic set of symptoms, known under the name of hepatic colic. Attacks of pain are frequently, though not always, the first symptom of the passage of gall-stones. The intensity of the suffering varies greatly in different cases. It may be so mild and ill-defined as not to suggest its true cause, or it may be unbearable.

A typical attack of hepatic colic either begins suddenly, or it has for prodromata nausea, chilliness, and mild constitutional disturbance. The most frequent time for its occurrence is a few hours after dinner. The pain may be violent from the start; or, if at first less severe, it quickly reaches an extreme degree. It is usually felt chiefly in the epigastrium and the right hypochondrium, but radiates thence backward and toward the shoulders, or even into the right arm. The pain comes in paroxysms, being worse each time till it becomes extremely severe. General convulsions have been repeatedly observed as a result of the pain, particularly in nervous individuals. Quite often there is a severe rigor. Vomiting is also common. Usually there is constipation. As a rule, there is great constitutional disturbance; there are extreme languor and weakness, with an appearance which suggests collapse. The pulse is small and somewhat accelerated; less frequently, it is slower than normal. The temperature is normal. During the rigor, however, it may be elevated to 104° (40° C.) or more. On physical examination, the liver is more or less enlarged; and sometimes it is possible to feel a full and distended gall-bladder, or at least to find a dullness on percussion corresponding to it. Jaundice often appears toward the end of the attack, but not invariably. Of course it can be caused by a calculus only when it blocks up the hepatic or common ducts. Occlusion of the cystic duct would not produce it.

The duration of an attack is, in mild cases, only a few hours, and in severer ones seldom more than one or two days. Probably the pain ceases the instant the stone has successfully passed the final narrow portion of the common duct, just above its opening into the intestine. Perhaps relief is sometimes due to the stone's slipping back again into the gall-bladder. If the feces are carefully examined after an attack is ended, we often find one or more calculi. The best method of search is to pour the feces upon a sieve, after adding water to them. In one or two instances, gall-stones have passed into the stomach and been

vomited up. The interval between different attacks varies. Sometimes months or years intervene, sometimes only a little while. Not infrequently there is a quick succession of attacks, and then none for years or even for a lifetime. In the intervals the patient may feel perfectly well, but he may have a slight jaundice or an enlarged liver or chronic digestive disturbance.

Permanent impaction of a stone at any point in the biliary passages gives rise to quite different phenomena. Usually the violent symptoms of hepatic colic persist for some days, but then abate, leaving behind only a dull pain subject to occasional exacerbations. Sometimes the symptoms almost all vanish, in case the passage is not entirely occluded. If, however, no bile whatever can pass, further trouble is to be expected. If the calculus lies in the cystic duct, mucus collects in the gall-bladder and gradually distends it. The coloring matter of the retained bile is gradually absorbed, so that finally the contents of the gall-bladder is an almost colorless mucous fluid. This condition, of course, arises just the same from occlusion of the cystic duct due to any other cause. It is termed dropsy of the gall-bladder. Sometimes the distended viscus can be felt through the abdominal walls. If a gall-stone lodges in the hepatic duct, or, as is much oftener the case, in the common duct, and dams up the bile, chronic jaundice is inevitable.

Another series of very important symptoms is due to the secondary inflammation or ulceration resulting from the impaction. A gall-stone may excite a secondary inflammation, no matter where it lodges, whether in the gall-bladder or the ducts, or in the liver itself. The phenomena are quite analogous to the inflammation which a fecal calculus excites in the vermiform appendix (*vide supra*). The first effect of the stone is purely mechanical. Its pressure causes a simple necrosis of the mucous membrane. The inflammation and ulceration are developed secondarily around the necrosed tissue; but once started, they may spread. The germs which excite the inflammation are probably in all cases derived from the intestinal canal. As long as the ulcerative process is confined to the mucous membrane there are no special symptoms; but quite often it gradually involves the deeper tissues or invades neighboring organs. In such cases the number of possible events is almost infinite. We shall mention here only a few of the most frequent and important.

If the gall-bladder or one of the large ducts is perforated, the bile flows into the abdominal cavity. Gall-stones also have more than once escaped in the same way. Such a perforation is almost invariably followed by a purulent and usually quickly fatal peritonitis. This is not excited by the bile itself, for normal bile does not provoke inflammation, but it is due to septic matter (or decomposed bile), which also gains access to the peritoneum. Rarely there is perforation outward. The inflamed gall-bladder forms adhesions to the abdominal walls, the ulceration slowly progresses, and finally reaches the surface of the body. Thus a genuine "external fistula of the gall-bladder" may be formed, through which bile and calculi are discharged. More frequent than either of these occurrences is perforation into neighboring organs, and into the duodenum in particular. Virchow, and more lately Fiedler, have pointed out that we can not explain the appearance of large gall-stones in the feces on any other supposition than that of duodenal perforation; for it is hardly supposable that calculi the size of a walnut or even larger should pass through the bile-ducts if in a normal state. Of course, the bile can also escape through this same abnormal opening, whereupon the symptoms of biliary retention and those due to lack of bile in the intestines cease. There have been a few cases of similar perforation into the stomach and the colon, and even into the portal vein and the urinary passages.

The clinical symptoms of all these secondary inflammatory and ulcerative processes may, of course, vary greatly. Sometimes the symptoms are for a long time

so indefinite that no diagnosis can be made with any degree of certainty. There are abdominal pain, occasional febrile attacks, constitutional derangement, and anorexia—symptoms which, to be sure, indicate some serious trouble, but do not reveal its nature. The case is different if there be a previous history of colic, jaundice, the appearance of gall-stones in the stools, or similar more definite indications. If perforation into the abdominal cavity takes place, acute and severe peritonitis is, as we have said, almost inevitable. If a perforation into other organs occurs, the only sign by which it can be recognized is the discharge of gall-stones through some unusual channel—for instance, through the abdominal walls, or the œsophagus, or the urinary organs. The "biliary abscesses" which may be produced in the liver by gall-stones will be considered under the general head of hepatic abscesses. It is worth while to mention, that in rare instances large gall-stones which have reached the intestinal canal cause obstruction of the gut. There have also been a few cases of secondary inflammation and ulceration of the intestine due to gall-stones.

**Diagnosis.**—It is evident from what has been already said that often the diagnosis of cholelithiasis is easy and indubitable, while in other cases the symptoms and course of the disease are obscure and ambiguous. The attacks of colic are certainly the most characteristic symptom. We should therefore make it a rule, in case of severe paroxysmal pain in the region of the stomach or liver, to think of the possibility of gall-stones. Any mild jaundice accompanying such an attack makes the diagnosis more probable. For absolute certainty, however, we need to find the stones in the dejecta; but even without this, in most of the typical cases, the disease may be correctly diagnosed. It is most easily confounded with cardialgia, intestinal colic, renal colic, and attacks of pure "neuralgia in the distribution of the hepatic plexus." Observation of the patient for a considerable time may often be required in order to reach a definite conclusion.

It is but seldom that physical examination of the liver in this disease yields decisive results. Still it is possible, as has been said, that a gall-bladder distended with calculi may be felt through the abdominal walls. Sometimes we can even hear with a stethoscope the friction of the stones upon each other.

**Prognosis.**—We have already enumerated the manifold dangers which are incident to cholelithiasis, but on the whole these untoward results seldom occur. As a rule, the termination is favorable. Either the calculi escape in some way, and there is complete recovery; or at least the symptoms abate, and the patient feels as well as ever, although the possibility of a relapse hangs over him.

As to the separate symptoms, the colic itself is very seldom dangerous. In a very few cases of extreme severity there has been a fatal collapse. Permanent obstruction of the common duct is worse, because it greatly impairs nutrition, and also leads to secondary changes in the liver (*vide infra*). The most favorable direction for a perforation to take is into the small intestine. It would seem that the fistula thus originated may even heal up perfectly. The ulcerative process may cause an unfavorable result by entailing a cicatricial closure of the common duct.

**Treatment.**—Our first efforts must be directed to a relief of the symptoms excited by the gall-stones. We must further endeavor to promote their discharge from the body and to prevent the formation of new ones.

It is the hepatic colic which most often demands therapeutic interference. The most important and indispensable remedy is opium or morphine. If there is violent pain, a grain of opium (0.05 grm.) is usually required every hour or two. If there is vomiting, or if immediate relief is called for, a sixth to a third of a grain (0.01-0.02 grm.) of morphine may be injected subcutaneously. Other narcotics, like chloral and belladonna, are seldom needed. In the way of external applications to the hepatic region, warm or hot poultices serve the best purpose.

Some few patients get more comfort from an ice-bag. Usually some relief can be obtained from a mixture of equal parts of chloroform and olive-oil rubbed gently in over the liver. Sometimes relief is obtained by a prolonged warm bath. For violent emesis, opium, potassic bromide, or bits of ice may be administered. In collapse, we must exhibit such stimulants as wine, strong black coffee, or even ether or camphor subcutaneously. After the colic is over, some mild laxative, such as a mineral-water, is generally given, to favor the evacuation of such calculi as may have entered the intestinal canal.

[When giving repeated doses of opium for biliary or renal colic, it should be remembered that the pain will cease abruptly as soon as the stone ceases to obstruct the passage, and that severe toxic effects of the drug may then appear. In bilious colic the distance to be traversed by the stone is relatively short, and in that affection especially the inhalation of ether or chloroform is sometimes the best, and, indeed, the imperative treatment.

The operation of cholecystotomy has now won for itself an enviable position in surgery, and in the hands of a skilled surgeon gives permanent relief at relatively small risk to cases of recurrent and persistent gall-stone impaction which are quite beyond the reach of internal remedies.]

The second indication, namely, to prevent the formation of fresh concretions, is best met by certain alkaline mineral waters. Just how they act is uncertain, but that they do exert a favorable influence has been satisfactorily established by experience. The springs of Carlsbad have gained the highest reputation of any. If the patient's circumstances permit, it is always best to send him to Carlsbad. During the "cure" there it often happens that a large number of gall-stones are passed with comparatively little discomfort, and the patient not infrequently returns home to enjoy for years, or even for life, freedom from his old trouble. Vichy is good, as are also Kissingen, Homburg, Marienbad, and Ems. If the patient can not travel, he must drink Carlsbad water at home for a month or six weeks.

All the other remedies are of dubious efficacy. "Durande's remedy," which is a mixture of three parts of ether and two parts of oil of turpentine, is much in vogue: twenty or thirty drops are to be given two or three times daily for a long while. The internal use of chloroform is also recommended. Ten or fifteen drops in some mucilaginous vehicle are given three or four times a day. Of newly suggested remedies, salicylate of sodium deserves especial mention. It certainly promotes the secretion of bile. It is given in long-continued small doses (30 grains to 1 drachm—2·0-4·0 grm.—*per diem*). Italian physicians highly praise the free use of olive-oil, say six or seven ounces (200·0 grm.) daily in divided doses. It is said that in obstinate and severe cases of hepatic colic the oil sometimes causes marked improvement.

[Most of the oil is passed in lumps, which have a superficial resemblance to gall-stones, and are sometimes called such.]

If perforation, peritonitis, or any other special complications arise, they are to be treated on general principles.

## CHAPTER III.

## SUPPURATIVE HEPATITIS.

*(Hepatic Abscess.)*

**Ætiology.**—Exclusive of traumatism there are two ways by which bacteria may penetrate into the liver, there to excite a suppurative inflammation—namely, by the blood and through the bile-ducts. In the circulatory system the main route is by way of the portal vein, by which germs from the intestines reach the liver. This explains why many ulcerative processes in the intestine, like severe dysentery, are followed by hepatic abscess; and why purulent pylephlebitis (*q. v.*) and other suppurative processes within the portal system may have a similar sequel. In general pyæmia, the germs must take a very circuitous route in order to reach the liver. They must, on leaving the primary abscesses, first enter the veins and the lungs, and then gain the liver by way of the hepatic artery. It has been well known for a long time that suppurating wounds of the head are followed by hepatic abscess with comparative frequency. Perhaps it may exceptionally happen that infectious matter enters the hepatic veins by “retrogressive embolism” from the vena cava.

The germs which make their way into the liver from the bile-ducts invariably originate in the intestine. In these cases the hepatic inflammation is almost invariably preceded by disease of the biliary passages. The most frequent cause by far of this variety of hepatic abscess is the formation of gall-stones. The two most essential factors are the mechanical injury caused by the concretion—that is, necrosis from pressure—and the decomposition of the retained bile.

Among us, hepatic abscesses are rarely occasioned in other ways than those indicated; but in the tropics it is said that quite a large number of apparently primary hepatic abscesses are met with. Their origin is not yet explained, although in this case also there is most probably an invasion of pyogenic bacteria from the intestine.

**Pathology.**—The smallest and as yet imperfectly developed abscesses best illustrate the mode of formation. We find the blood-vessels choked with micrococci, and the cells of the surrounding parenchyma void of nuclei and in process of disintegration. Along the course of the blood-vessels nuclei are very abundant. These are due to white corpuscles which have escaped through the vascular walls. The cells and the liquid exudation rapidly increase, and there is complete destruction of the hepatic parenchyma, and the formation of an abscess in its place. This may extend indefinitely in all directions. Large abscesses may at last involve an entire lobe. In other cases the suppurative process is limited by encapsulation. Sometimes quite large portions of the liver become necrotic and slough off, under the influence of what is called “sequestrating” suppuration. We almost invariably find some shreds of hepatic tissue in the pus of hepatic abscesses. Where the abscess is due to gall-stones, the latter are found in the pus.

Small abscesses may be absorbed, but they are often merely symptomatic of pyæmia or some such disease, which is itself incurable. Larger abscesses may point into neighboring organs. If they are discharged into the abdominal cavity, diffuse peritonitis follows. The most favorable termination, and one repeatedly observed, is perforation through the abdominal walls, after these walls and the liver have been joined by adhesions. They may also break into the pleural cavity, the pericardium, the intestine, and the pelvis of the right kidney.

**Clinical History.**—An absolutely complete clinical description of hepatic abscess is impossible, because, as we have seen, it may be a symptom of such

diverse pathological processes. Hepatic abscesses are often found post mortem which had given no previous indication of their presence; this is frequently true in pyæmia. In other cases there are symptoms, in part directly referable to the seat of inflammation, and in part due to its influence upon neighboring organs.

Enlargement of the liver can often be made out by percussion or even by palpation. It is the result of swelling and hyperæmia involving the entire organ. Extensive abscesses may give much more definite signs of their presence, however, if situated near the anterior edge of the organ. They are sometimes felt through the abdominal walls as hemispherical and actually fluctuating tumors. It is not so very rare for tropical hepatic abscess to attain these dimensions.

Pain in the right hypochondrium, although it may be entirely absent when the abscesses are small, even if they are numerous, is often violent and persistent when the abscess is large. It is excited by the tension of the peritoneal covering of the liver, or by a perihepatitis. The pain often radiates,—and with especial frequency, it is said, into the neighborhood of the right shoulder.

The course of the fever may prove a strong diagnostic point. When the abscess is chronic and encapsulated there may, it is true, be no fever whatever; but, as a rule, fever does exist, and often presents a very characteristic intermittent character. There are great elevations, usually ushered in by a chill, and succeeded by deep depressions of temperature accompanied by perspiration. If the hepatic trouble is merely a symptom of general pyæmia, then the fever is to be ascribed to the latter; but if there are signs of a severe local hepatic disease, such as pain, enlargement, and jaundice, and if these febrile attacks come on at irregular intervals, we should always consider the possibility of abscess of the liver. In the cases of large tropical abscess this sort of fever is the rule. It is most frequent with us in cases of purulent pylephlebitis and of abscess excited by gall-stones. The "*fièvre intermittente hépatique*" of the French is in most instances due to the presence of gall-stones in the liver, with secondary suppuration.

Among the secondary symptoms of hepatic abscess jaundice is prominent. It is not invariably present, however, occurring only when the abscess has compressed some large biliary duct, and has thus given occasion to the absorption of bile by the lymphatics. In rare instances the abscess compresses the portal vein and thus causes ascites. There may be pulmonary symptoms of considerable importance, even when there are no actual pulmonary complications. This is because the right half of the diaphragm is crowded up by abscesses projecting from the convex surface of the liver. Hiccough is sometimes a source of distress, and may be due to the pressure of the abscess upon the stomach. Vomiting is also a rather common and often very troublesome symptom.

There is almost always great constitutional disturbance. The patient has no appetite, and loses flesh, particularly if there are frequent febrile exacerbations. Often there are severe nervous attacks. Very exceptionally, the disease remains latent for a long while, and does not disturb the general health to any great extent.

The course of the disease depends mainly upon the nature of the original disturbance. Severe pyæmic cases, in the course of which hepatic abscesses develop, are generally brief, and are almost invariably fatal. Abscesses due to gall-stones, and the large abscesses which are apparently idiopathic, are generally chronic, lasting for weeks, or even for many months. Cases exhibit manifold diversities, according to the position, size, number, and sequelæ of the abscesses. Among the possible results, we would once more call attention to perforation into neighboring organs. If the pus is discharged externally, recovery may ensue; as also if the pus reaches the intestinal canal or the bronchi, which seldom happens. Perfora-

tion into the abdominal cavity always excites a fatal acute peritonitis. As a general rule, hepatic abscess finally proves fatal, recovery being exceptional. Death is due either to the gradual loss of strength or to some complication.

**Treatment.**—Local bleeding, counter-irritation, purgatives, and emetics are among the remedies which are advocated, but we can hardly expect them to exert much influence upon a hepatic abscess. The best way is to treat the case purely symptomatically, seeking to keep up the patient's strength and mitigate his suffering until, if we are very fortunate, we have a chance for operative interference. When once the other symptoms are re-enforced by the discovery on palpation of a fluctuating tumor, the diagnosis is established, and the pus should be evacuated and the cavity drained. Particulars about the operation should be sought in works on surgery. More than one case of the large tropical abscess has been cured in this way; but the cases which are most common among us—namely, embolic abscesses and those excited by gall-stones—hardly ever afford any opportunity for surgical interference.

#### CHAPTER IV.

##### CIRRHOSIS OF THE LIVER.

(*Chronic Diffuse Interstitial Hepatitis. Laennec's Cirrhosis. Gin-drinker's Liver.*)

**Ætiology and Pathology.**—Cirrhosis of the liver is usually defined as a diffuse interstitial inflammation, chronic in duration, and resulting in a secondary atrophy of the true hepatic parenchyma. This conception makes the disease perfectly analogous to "chronic interstitial inflammation" of the kidney and many other organs. Weigert's careful study of the processes of "chronic interstitial nephritis" has shown that at least a large part of the changes which take place in the connective tissue are not primary, but secondary, and the consequence of a primary destruction of the genuine renal parenchyma. The question naturally suggests itself, whether the same may not be true of the apparently closely allied phenomena of hepatic cirrhosis. We feel justified, therefore, in seeking the origin of the disease in a primary injury and consequent partial destruction of the hepatic cells, whereupon follow a secondary proliferation and final contraction of the interstitial tissue, just as is seen in lesions of the parenchyma of the kidneys, spinal cord, and heart.

Such a conception would be extremely compatible with one fact about the ætiology of the disease, namely, that chronic alcoholism is universally regarded as a potent predisposing cause. Hence the English name, "gin-drinker's liver." The harmful influence of alcohol can be appreciated, if we remember that on being absorbed it is carried directly by the blood-vessels to the liver. The stronger liquors are more potent for evil in this direction; wine and beer are not harmless, however. According to the usual view of the disease, the poison excites a chronic inflammation of the connective tissue; while, according to the new view, the alcohol exerts a specific injurious influence upon the hepatic cells proper, impairing their nutrition, and finally causing their destruction. That the disease attacks the periphery of the lobules and the interlobular connective tissue is equally consonant with either theory. It is well known that the capillary anastomoses of the portal vein are situated between the lobules.

The abuse of alcohol is by no means the only cause of cirrhosis, for quite often the disease attacks persons in whose case no such ætiology is possible. In such

instances we are seldom able to demonstrate the real cause. The excessive use of spices, and other analogous substances, has sometimes been regarded as causative. It is also said that sometimes malaria, and the acute infectious diseases, leave behind them a tendency to cirrhosis. The form of cirrhosis which follows diseases of the bile-ducts, and also "syphilitic cirrhosis," will receive separate consideration.

Cirrhosis of the liver is seen much oftener in men than in women, and usually occurs in middle life.

The anatomical changes are generally divided, without regard to the way in which they are brought about, into two stages. In the first stage the liver is uniformly enlarged, resistant, with its edge blunt, and its surface at first perfectly smooth, but later presenting little dimples. On section, the increased consistency, or "interstitial induration" of the liver, can be readily perceived. The acini are separated from one another by a relatively thick band of grayish-red interstitial tissue, and are at first readily distinguishable. Later on, the interstitial hyperplasia invades the acini themselves, and they cease to be discernible. The microscope shows that the cause of this increase in size and firmness of the organ is due exclusively to the abundant cellular infiltration and the new formation of connective tissue between the individual lobules. The neighboring cells of the parenchyma exhibit signs of disintegration, undergoing either simple atrophy or else fatty degeneration.

The second stage corresponds with the process of contraction of the newly formed connective tissue, but in this stage the destruction of the proper hepatic tissue has already assumed grave proportions. On the old theory, the parenchyma perishes because of the great disturbance of circulation in the portal capillaries, great numbers of which are obliterated by the shrinking of the connective tissue. Under this process of contraction the liver undergoes progressive atrophy, and its surface becomes mammillated. The size of the nodules varies. The size of the whole organ may be reduced one half, or even more. Frequently its general contour is considerably modified. Upon microscopic examination, we now find merely vestiges of parenchyma, embracing which are wide, firm bands of connective tissue. Even within the acini there is decided interstitial hyperplasia along the blood-vessels. Brown masses of pigment are often found here and there, which have been left behind by the hepatic cells now destroyed. Regenerative changes can also be detected quite frequently. The most common of these is the formation of small biliary passages in the broad bands of interstitial tissue.

The division of hepatic cirrhosis into two stages is somewhat diagrammatic, for there is really no sharp dividing line between them. The same liver may in different places illustrate both stages simultaneously. Thus, the surface is often distinctly granular, while the liver as a whole remains hypertrophic.

**Clinical History.**—The onset of the disease is usually insidious. At autopsies, quite an advanced stage of cirrhosis is sometimes found, to which not a single clinical symptom had pointed; and it is often observed that the duration of unambiguous symptoms is much shorter than the degree of anatomical change discovered post mortem would have led us to expect.

It is, however, true that certain prodromata may appear long before the genuine cirrhotic symptoms; but there is generally room for doubt whether these prodromata are excited by the incipient hepatic disease or whether they are not due to other coincident affections, such as the chronic gastric or intestinal catarrh which drunkards so often have. There are anorexia, nausea, epigastric uneasiness, eructations, constipation, and sometimes vomiting. There is evident constitutional disturbance in many cases, but in others the strength is unimpaired. The severer symptoms usually date from the time when disturbance of the portal circulation

arises. We have already stated that the diseased process is most active in the interlobular connective tissue—that is, where the portal capillaries are situated. When the contraction of the connective tissue has resulted in the destruction of a large number of these portal capillaries and the minute veins from which they spring, the portal circulation is inevitably impeded, and there arises a passive congestion of the whole portal system. The signs of this are soon manifest.

The stasis in the veins of the peritoneum is, as a rule, the first to attract attention, from the ascites which it occasions. The distention of the abdomen and the sensation of weight and pressure due to this effusion, are often the first things which excite the patient's attention and lead him to seek medical advice. Later on, the ascites sometimes becomes enormous, causing immense swelling and extreme tension of the abdominal walls, and, of course, proportionate discomfort. Proper nursing and internal treatment may diminish the ascitic effusion, but they will seldom wholly remove it. It quite often remains nearly uniform, until finally, for some reason, there is a change for the worse.

Next to ascites, the most important symptom of portal obstruction is enlargement of the spleen, which is due both to the increased amount of blood in the organ and to a diffuse hyperplasia of its tissues. As a rule, the increase in size is considerable, amounting sometimes to two or three times the normal dimensions. The demonstration of splenic tumor is of great diagnostic importance, but is often a difficult matter. Percussion and even palpation are greatly interfered with by the co-existing ascites. On the whole, however, palpation is the more reliable. Pain or other subjective symptoms are rarely observed. Exceptionally, there is no enlargement of the spleen. This may be due to the firmness and thickness of its capsule, or to the general marantic condition of the patient.

The venous congestion of the stomach and intestine excites catarrh, which is evinced by anorexia, nausea, and irregularity of the bowels. Usually there is quite obstinate constipation, but there may be persistent diarrhœa. None of these symptoms occupy the foreground of the clinical picture, however, both because they are frequent in all grave chronic diseases and because many patients have had digestive derangements long before these severer troubles began. A more significant symptom, if it occurs, is hæmorrhage. This is now and then occasioned by the extreme gastro-intestinal congestion. The bleeding may be from either the stomach or the intestine, and is sometimes a relatively early phenomenon. Sometimes there is a capillary oozing sufficient to tinge the stools day after day for some time. Very rarely there is hæmorrhage from the œsophagus.

The patient may be moderately jaundiced even in the common form of cirrhosis. This is sometimes due to duodenal catarrh. Often there is no jaundice whatever; or there may be a slight yellowish tinge of the skin, in addition to the dirty, grayish, earthen color which not infrequently characterizes the cirrhotic. Perhaps the jaundice is due in many cases to stenosis of the intra-hepatic bile-ducts, involving biliary retention.

The above signs of portal obstruction will often render the diagnosis of hepatic disease extremely probable, but we should always endeavor to confirm our opinion by physical examination of the liver. In the later stages of the disease, and particularly if there be great ascites, our efforts may be fruitless; but at first, or after paracentesis has been performed, percussion and palpation may yield valuable information. In the earliest stages the liver is large. Hepatic dullness reaches some ways below the edge of the ribs, and we can often feel the lower edge and anterior surface of the organ. Later on we find the surface irregular and rough. If we can feel these little nodules or prominences through the abdominal walls, as we sometimes can, of course the diagnosis of cirrhosis of the liver is nearly certain. As already mentioned, it often happens that irregularities

are already to be felt upon the surface of the organ while it still remains hypertrophic. The demonstration of atrophy by percussion in the later stages of the disease is less reliable. The ascites often interferes with such an attempt. We may also be misled by coils of intestine distended with gas and perhaps lying in front of the liver. If, however, after guarding against error, we constantly find the area of hepatic dullness diminished, the sign has some value.

General nutrition is usually much impaired in the later stages of the disease. At first the patient may retain vestiges of his former corpulence, but finally he grows emaciated. Anasarca may exceptionally occur toward the close; but there is frequently considerable œdema of the lower extremities, and even of the scrotum and the dependent portions of the abdominal walls. The cause of this is a purely local one—the pressure of the ascites impedes the return of blood from the lower limbs to the heart.

Occasionally there are ecchymoses into the skin, the mucous membranes, the retina, and other parts. These are probably due to malnutrition of the vascular walls.

Unless there are complications, there is no fever. Respiration may be impeded and accelerated on account of the upward displacement of the diaphragm. The pulse is usually small, and often somewhat more rapid than normal.

At first the urine presents no characteristic changes. When the ascites has become considerable and there is œdema, the urine grows scanty, dark, and concentrated, and often has an abundant sediment of urates. It should be mentioned that earlier observers found a diminished excretion of urea. This is perhaps due to a disturbance of the urea-generating function of the liver, about which both earlier and more recent investigators agree. In a few instances the urine has been found to contain a trace of sugar.

It remains for us to describe briefly the collateral circulation which may be developed in cirrhosis, so as to enable the blood of the portal system to reach the systemic veins. The clinical history of the disease does not indicate that this attempt at compensation is very successful. We may have: 1. Communications between the veins of the mesentery and of the abdominal walls. 2. Communications between the coronary vein of the stomach and the veins of Glisson's capsule on the one hand, and the phrenic veins on the other. 3. Anastomoses between the internal hæmorrhoidal and the hypogastric veins. 4. As pointed out by Baumgarten, enlargement of the not yet completely obliterated umbilical vein in the ligamentum teres. Through all these the blood may flow from the portal system into the veins of the abdominal walls—that is, in the reverse of the normal direction. In cases of portal obstruction the veins of the abdominal walls are often much enlarged, and this may be partly due to the changes just enumerated. In some instances the veins around the umbilicus have been strikingly tortuous and swollen; this condition has been termed "*caput Medusæ*."

The complications which sometimes occur are probably in part due to the same injurious influences as the cirrhosis. This is apparently true, for example, of the cardiac hypertrophy, the contracted kidney, and the chronic pachymeningitis. An interesting combination is the simultaneous occurrence of cirrhosis and chronic tubercular peritonitis. Various observers as well as ourselves have observed this with comparative frequency. The explanation is unknown. Probably cirrhosis is the primary lesion, and it promotes the development of peritoneal tuberculosis through the passive congestion of the portal system. Sometimes, however, the order of development seems to be reversed.

As to the general course of the disease, its duration can not easily be determined because the onset is usually insidious. As a rule, the disease lasts one to three years, or rarely longer. In many cases the symptoms are insignificant for

the first six to eighteen months. Then the disorder takes on a severer form, perhaps rather suddenly. Ascites appears, for example. These graver symptoms persist, till after a few months the patient dies. The course of the disease reminds one of cardiac cases, where for a long while the compensatory changes avert any distress, till on a sudden the circulatory disturbances become pronounced and persist to the end.

The prognosis is always unfavorable, at least when the symptoms have once become well marked. It may be that in the earlier stages the disease can be checked or even permanently cured; but even this is open to doubt. No case recovers in which the diagnosis of cirrhosis is certain.

Death is due either to intercurrent disease, or more often to gradually increasing exhaustion. In some few cases severe cerebral symptoms suddenly appear: there are coma, general convulsions, and delirium; and these usually are soon fatal. Just how these nervous phenomena originate we do not certainly know (see the chapter on acute yellow atrophy of the liver).

**Diagnosis.**—The diagnosis is seldom very easily made. It becomes extremely probable if a patient who is known to have been addicted to alcohol gradually develops ascites and splenic tumor, and has a liver which presents distinct evidences of disease, such as an irregular surface. Often, however, we are left in doubt, because one or another of these more characteristic symptoms can not be clearly made out. Often a patient does not come under observation till a considerable ascitic effusion has already taken place, so that physical examination of the liver and spleen is rendered very difficult. Then we must first exclude any general disturbance of circulation as a cause of the ascites. If the heart, lungs, and kidneys are found to be normal, and if there is no œdema in the upper half of the body, it is very probable that there is a local derangement of the portal circulation; but we have still to determine whether the cause of this derangement is cirrhosis of the liver. This may be assumed to be the case if the whole course of the disease warrants the assumption, and if the history furnishes that most frequent of all ætiological factors, chronic alcoholism. Otherwise we must be cautious, for portal obstruction with precisely similar results may be due to other causes—like the external pressure of tumors or portal thrombosis. Many forms of hepatic syphilis (*q. v.*) can not be differentiated from cirrhosis by mere clinical observation of the hepatic disorder. Here it is only the ætiology and the demonstration of other signs of syphilis that can justify the assumption that the disease in hand is of specific origin.

It is also very difficult in many instances to exclude chronic peritonitis. The ætiology may aid us. Other points are, that in chronic peritonitis there may be tenderness on pressure, the abdominal distention is less uniform, and there is no enlargement of the spleen. The combination of cirrhosis and chronic tubercular peritonitis can not be diagnosticated with any approach to certainty unless we find both the symptoms of cirrhosis and pronounced indications of a tubercular affection. In such a case coincident pleurisy is significant of tuberculosis.

**Treatment.**—As we know the causes which sometime excite cirrhosis of the liver, an obvious prophylaxis consists in avoiding them; and, even after the early symptoms of the disease have appeared, alcohol should be forbidden, as well as spices and other similar articles, in the hope that we may thus do something to prevent the extension of the abnormal process.

If the disease has already made considerable progress, treatment becomes purely symptomatic. Iodide of potassium is said to exert a favorable influence upon cirrhosis of the liver, but its powers are doubtful. Probably it does good only in syphilitic hepatitis. Of the individual symptoms the results of portal congestion deserve the most consideration. It is important that the patient should

enjoy complete physical rest, and that his bodily vigor should be promoted in every way possible. Even by these means we are sometimes able to diminish, or at least prevent the increase of, the ascites and other effects of portal obstruction.

Further remedies are given with the purpose (1) to deplete the congested portal system, and (2) by promoting the watery excretions to cause reabsorption of the ascitic effusion. Depletion is usually attempted with purgatives, the action of which is expected to diminish the high tension existing in the portal vein. The custom is an old one. In the milder cases, just developing, salines are recommended, usually in the form of mineral waters. The continued use of small doses of calomel (say 2 or 3 powders a day, each containing one half to one grain—0.03–0.05 gm.) seems to be sometimes advantageous. But if the ascites is already great, it is claimed that drastic remedies sometimes prove beneficial. Gamboge is reputed to be particularly appropriate in cirrhosis. We should not persist in the use of such drugs, however, if they disturb digestion.

The second indication of promoting watery discharges is fulfilled by diuretics. Besides the usual remedies of this class, like potassic acetate and squills, copuiba and its resin have been especially recommended for the various forms of ascites by English authors. The dose [of the resin] is about fifteen grains (gm. 1) daily, best given in capsules. In some cases this remedy has caused a rapid increase in the amount of urine and an accompanying diminution of the ascites. The improvement is not permanent, however. Good diuretic effects are sometimes obtained with calomel (*vide* p. 306).

If the ascites is so excessive as to occasion much local discomfort and to impede respiration, the removal of the fluid by paracentesis may afford relief. The details of this proceeding were given in the last section. Many physicians recommended tapping as early as possible, before it is absolutely necessary. The relief is said to be more lasting in that case; but, as a rule, the abdomen generally is quickly filled again. Possibly the application of an elastic bandage after the fluid is removed may retard its reaccumulation by the pressure thus exerted upon the abdominal cavity.

Special symptoms may sometimes demand attention. They are to be treated according to general principles.

---

## CHAPTER V.

### BILIARY AND HYPERTROPHIC CIRRHOSES OF THE LIVER.

THERE are two forms of cirrhosis which differ in many respects from the disease just described: they are called biliary cirrhosis and hypertrophic cirrhosis of the liver. Charcot and other French investigators were the first to call attention to them. Since then the literature of the subject has become quite considerable, but all doubts and differences of opinion are not yet settled. We shall try to state the most important points in what follows.

Whenever there is retention of bile in the liver for any length of time, no matter what causes it, certain changes result. The small and the medium-sized bile-ducts become distended, and granules of pigment are deposited, both in the interlobular connective tissue and within the acini themselves. Besides this, however, and undoubtedly because of the noxious influence of the retained bile, the hepatic cells undergo destructive changes. In accordance with the general rule, connective tissue gradually fills the gaps thus left in the parenchyma, and, more than this, the interstitial hyperplasia is so great as to increase the size of the organ.

If, therefore, there is persistent obstruction of the common duct by a gall-stone, or a cicatricial stenosis, or a tumor pressing from without upon the duct, the liver will, in all such cases, be found to be larger, firmer, and richer in fibrous tissue than normal—in a word, "cirrhotic." Hence this condition does not represent an independent disease, but is a result of chronic biliary retention, in whatever way occasioned. It is appropriately termed "secondary biliary cirrhosis." That retention is really the cause of this change has been proved by experiments, for it has been shown that ligature of the common duct in animals causes well-marked biliary cirrhosis.

This secondary cirrhosis is due to occlusion of the large bile-ducts. There is also a rare primary form of the biliary cirrhosis, usually known as hypertrophic cirrhosis. French authors have given it the name of "*cirrhose hypertrophique avec ictère*," out of regard to its most important clinical symptom. That there is an essential difference between this form and the ordinary "atrophic" cirrhosis of Laennec is manifested by the clinical behavior of the disease.

Often this disorder attacks hard drinkers, but they are not its only victims. While, in the common form of cirrhosis, ascites is usually the earliest grave symptom of disease, in hypertrophic cirrhosis a slight jaundice generally appears simultaneously with the first indefinite symptoms of pressure in the region of the liver, languor, and anorexia. This jaundice rapidly increases, and persists throughout the illness. In ordinary cirrhosis there may be, as we have said, hardly any jaundice, or, at any rate, it is a rather late symptom, and even then it is seldom extreme. On the other hand, ascites may be slight or absent in hypertrophic cirrhosis. It is true that there have been cases with great ascitic effusion, but it never comes till the disease is quite far advanced.

On physical examination the liver is usually found to be considerably enlarged, and its surface is smooth, as a rule, or rarely rough. In general there is said to be this important difference between the ordinary and the hypertrophic forms, that in the latter the newly formed connective tissue evinces little tendency to contraction, so that the liver remains large, even late in the course of the disease, and does not shrink. Somewhat too much stress has been laid upon this point. If, in many cases of hypertrophic cirrhosis, the liver has remained large to the end, this is probably in part due to an early death, before there was opportunity for much shrinkage. Cases that lasted longer have presented a contracted liver.

It must be said that the pathological appearance of the liver, particularly in the later stages of the disease, affords no certain evidence as to whether the cirrhosis was of the ordinary or of the "primary biliary" variety. Clinically, however, the two forms present such important diversities as to justify the distinction made. Of course, the clinical peculiarities of primary biliary cirrhosis must be due to some anatomical lesion. The most noticeable peculiarity of this sort is, that the development of connective tissue in hypertrophic cirrhosis is more active within the lobules than is the case in ordinary cirrhosis. Probably the hyperplasia in hypertrophic cirrhosis is most vigorous at first around the small biliary ducts, and thus leads to a retention of bile within the minutest biliary passages, with consequent jaundice, while the ramifications of the portal vein are not encroached upon till the process is far advanced. Whether these two forms of cirrhosis are merely modifications of one disease, or whether they are two independent disorders, is as yet unsettled. Certainly there are transitional forms.

As to the other clinical symptoms of primary biliary, or hypertrophic, cirrhosis we need say little. The most noticeable symptoms besides the hepatic enlargement and the jaundice are the effects of the jaundice itself—namely, digestive disturbances, slowness of the pulse, and nervous disorders. Of the occasional disturbances in the portal system, we have mentioned the ascites already. Still

more frequent, and usually earlier in the time of its appearance, is chronic passive congestion of the spleen, with enlargement.

The entire duration of the disease is about one or two years; but it may last much longer. The prognosis is almost always bad. Occasionally a case will exhibit marked temporary improvement or an apparent arrest of the disease. Death comes as a result of gradual exhaustion, or is suddenly ushered in by coma, convulsions, and other grave nervous symptoms, usually ascribed to cholæmia (*vide infra*).

The diagnosis of hypertrophic cirrhosis can sometimes be made with considerable positiveness, and sometimes can merely be regarded as probable. The gradual development and persistence of jaundice and the presence of an enlarged liver and spleen, but usually without ascites, would suggest the disease strongly; but in some cases it is often impossible to exclude the existence of some mechanical obstruction in the larger biliary passages, such as gall-stones or new growths.

The treatment should conform to the principles laid down in the chapters on jaundice and ordinary cirrhosis of the liver. Sacharjin has lately recommended the frequent use of small doses of calomel—one grain (0·06) several times a day.

## CHAPTER VI.

### ACUTE YELLOW ATROPHY OF THE LIVER.

**Ætiology.**—Acute fatty degeneration of the liver occurs both as a primary disease and as secondary to other hepatic disorders, or as a symptom of constitutional diseases. Secondary acute fatty degeneration in rare instances accompanies severe acute infectious diseases, like typhoid fever, recurrent fever, septicæmia, and puerperal disease. It also appears, with equal rarity, in the course of cirrhosis of the liver or of persistent biliary retention; and it is a constant phenomenon in acute phosphorus poisoning. Indeed, the effects of phosphorus resemble the symptoms of primary acute yellow atrophy in many ways so closely, even post mortem, that formerly the two were often confounded.

Primary acute yellow atrophy of the liver is an extremely severe disease which almost invariably leads to speedy death. There is generally no determinable cause, and its victims are struck down in blooming health. It is so rare that not much over two hundred cases have thus far been reported. It is most common in young adult life, say between the fifteenth and thirty-fifth year. Children and elderly people have been occasionally attacked. Females are much more liable to the disease than males; and pregnancy increases the predisposition to it.

As we have said, we can not as a rule find any exciting cause. It is stated that sometimes the onset has been preceded by some violent emotional excitement, or excess in alcohol, or the like; but how important these factors may be is not at all clear.

It is an interesting fact that sometimes the disease becomes rather more frequent than usual, and endemic. For instance, several members of one family will be attacked. This favors a view as to the nature of acute yellow atrophy which a majority of the present investigators seem inclined to adopt. The view referred to is suggested not only by the whole course of the disease, but by the pathological appearances, and places it in the category of acute infectious diseases. It must be confessed that as yet we know nothing about the intimate nature of the infection. Klebs maintains that he has discovered micrococci in the hepatic blood-vessels; but thus far the observation lacks confirmation.

**Pathology.**—The chief change found post mortem is in the liver, and has determined the name given to the disease.

The liver is much atrophied, sometimes being only one half or one third its normal size. This makes its capsule often seem contracted and wrinkled. The organ is usually soft and flabby, so that in some places it seems as if the finger could be pressed into it. The color of the surface, and for the most part of the cross-section also, is yellow, like ochre or saffron; but the cut surface may be part-colored, having red and yellow spots interspersed. Hence the names "red atrophy" and "yellow atrophy." The arrangement and relative extent of these patches may vary exceedingly. The red places look as if they had collapsed, and seem tougher than the yellow. They correspond, as we shall soon see, to the more advanced stages of the affection, while the yellow spots have undergone less change. The lobules are, as a rule, no longer distinguishable by the naked eye. Such lobules as can still be made out seem abnormally small and have a gray periphery.

On microscopic examination, we find that the essential change is an intense and uniform fatty degeneration of the hepatic cells, affecting the entire parenchyma. But few cells still retain their normal condition. The others are filled with large and small fat-globules, and many are already suffering evident disintegration and absorption. Where the degeneration is furthest advanced, fat, detritus, and pigment alone remain. Inasmuch as the lymphatics rapidly absorb and remove the fatty and albuminoid granules, there is finally little left except blood-vessels and connective tissue. The blood-vessels are frequently quite congested, and thus occasion that red color which the naked eye detects in the more advanced, broken-down portions. Frerichs made an interesting discovery, which deserves mention, of the existence of leucine and tyrosine crystals both in the parenchyma and in the blood-vessels. Bilirubin crystals also are sometimes found in the detritus, and more rarely in the interior of the hepatic cells.

Not only the liver, but many other organs present fatty degeneration: the heart in particular, the kidneys, and rarely the muscles; but the process is always most intense in the liver. The skin (*vide infra*) and most of the viscera are evidently tinged with jaundice.

Acute splenic tumor is invariably present. This suggests that the disease may be infectious. That the disease is a constitutional one is also to be inferred from the numerous ecchymoses in the skin and the interior of the body, especially in the mucous membrane of the stomach and intestines, in the serous membranes, in the pelvis of the kidneys, and the kidneys themselves, and more rarely in the brain and heart. This, again, is like the grave septic diseases. The blood itself is dark, with few clots. Leucine and tyrosine have repeatedly been detected in it. The peritoneum and other serous cavities sometimes contain a considerable amount of serum.

**Clinical History.**—The disease is usually divided into two stages, the first of which corresponds to the milder prodromal symptoms, the second to those severe symptoms which are alone characteristic. In many instances, however, the first period is wanting, or is so brief that the patient is plunged almost without warning into the gravest condition.

The prodromata in most cases consist of constitutional disturbances and mild gastro-intestinal symptoms. The patient is languid, without appetite, and disinclined to exertion. There are headache, nausea, vomiting, and sometimes moderate fever. In a few days jaundice usually appears. This is almost invariably taken for an ordinary catarrhal attack.

After some days, or it may be weeks, the second stage begins. The chief characteristic of this is the occurrence of grave nervous symptoms. First there

is violent headache, with sleeplessness and marked restlessness. The intellect is usually somewhat dulled even now, and articulation is slow and clumsy. The mental confusion usually advances very rapidly to a noisy and violent delirium. The excitement becomes at times maniacal. The patient screams and storms, and can hardly be kept in bed. Often there are convulsive twitchings of individual muscles; and there may be typical epileptiform attacks, but this is not common. After one or two days, or rarely longer, the excitement abates, and is followed by sopor, which soon passes into deep coma. At death the patient is usually perfectly unconscious. It is exceptional for the excited stage to be wanting; in such cases the first nervous symptom is sopor.

The cause of the nervous symptoms has not yet been explained in a way to silence discussion. The same theories which have been set up to account for the grave form of jaundice in general (see appendix to this chapter) have also been employed to elucidate the nervous phenomena of acute yellow atrophy. Thus, some refer them to cholemia, some to acholia, and still others to acute cerebral anemia. It seems to us worth considering whether the cerebral disturbance in acute yellow atrophy of the liver may not be due to the constitutional infection (or intoxication) which we have seen to be so probable.

The jaundice, which is present even in the first stage, afterward usually deepens. The urine contains bile-pigment, and many investigators have also found bile-acids in it. If these latter are present, it suggests that the jaundice is not hæmatogenous—that is, the result of a destruction of red blood-corpuscles and the transformation of their pigment into biliary coloring matter—but is rather due to a retention of bile. Just how this retention arises we do not yet know for certain. The obstruction can not be in the large bile-ducts, for the gall-bladder is usually found empty. Hence the cause of the retention of bile and of the jaundice is probably a derangement of the smaller biliary passages within the liver. We should add that in a few rare cases there has been little or no jaundice.

On physical examination of the liver during the last stage of the disease, there is usually a striking diminution of hepatic dullness, corresponding to the atrophy of the organ. Generally the first change to be detected is a contraction of the left lobe, as shown by the development of tympanitic resonance in the epigastrium. At the commencement of the illness, the hepatic dullness is normal or slightly increased in area. If the disease proves very rapidly fatal, the organ may never become very small. In most cases, though by no means in all, there are pain and tenderness in the hepatic region, but these are seldom so great as in phosphorus poisoning.

The enlargement of the spleen has been already mentioned as an almost constant symptom of the disease. Even during life some increase of the area of splenic dullness can usually be made out, and sometimes the spleen can be felt under the edge of the ribs.

The occurrence of the hæmorrhages, which have already been referred to under the pathological lesions, can often be demonstrated during life. The cutaneous ecchymoses can, of course, be seen, and the hæmorrhages in the mucous membranes may give rise to hæmatemesis, bloody stools, bleeding from the female genitals, or epistaxis. The hæmorrhages are probably due to the impaired nutrition and diminished resisting power of the vascular walls occasioned by the grave constitutional disturbance.

The condition of the urine in acute yellow atrophy is very interesting. The amount is either normal or slightly diminished, and the specific gravity is somewhat increased. Often there is a trace of albumen. We have already mentioned the presence of bile-pigment. The point of chief interest, however, is one that Frerichs discovered and various others have since confirmed, and is the great

diminution of urea and the appearance in its place of several other substances, which are likewise the products of the decomposition of albuminoid matter, and represent, in all probability, the first steps in the formation of urea. Of these substances, the most important are leucine and tyrosine. Their characteristic crystals

FIG. 52. —a. Leucine crystals. b. Tyrosine crystals.

can often be detected by the microscope in the urinary sediment (see Fig. 52). The crystals may also be obtained by allowing a drop of the fresh urine to evaporate slowly upon an object-glass. There is a chemical test for them which we can not here describe. There are some other abnormal constituents to be found in the urine besides leucine and tyrosine; but what their significance is we do not know. Among these are sarcolactic acid, oxymandel acid, peptonoid substances, and large amounts of kreatine.

It at once suggests itself that this disappearance of urea and appearance of leucine and tyrosine, which are regarded as preparatory stages in the formation of urea, gives valuable support to Meissner's and Von Schröder's idea that this substance is manufactured in the liver.

As to the other organs little need be said. Vomiting is very frequent in the second stage, as well as in the first. It usually ushers in the severe cerebral symptoms. The stools are, as a rule, clay-colored, as is usual in jaundice. There is generally constipation. The pulse is rapid often reaching 140 to 160 beats per minute, and is also small and compressible. It is this acceleration of the pulse, contrasting with its usual slowness during the first stage, which, along with the vomiting, announces the onset of dangerous symptoms. The pulmonary signs are seldom marked, although there may be bronchitis or a pneumonia due to the inhalation of foreign substances. During the coma which precedes death respiration is usually hurried, and often deep and noisy. Sometimes it is irregular.

The temperature is generally approximately normal. Toward the fatal termination there may be a subnormal temperature. Still more frequently the temperature rises before death, and even sometimes grows higher after death, reaching 107.5° (42° C.) or more.

In case the disease attacks a pregnant woman, abortion or premature delivery is almost certain to occur.

The entire duration of the disease depends mainly upon the length of the first stage. This may be entirely absent, or may be brief, or may occupy several weeks. The duration of the second stage, reckoning from the occurrence of grave cerebral symptoms, is generally only a few days (two to four), rarely a week. The termination is invariably fatal. In the few cases of recovery reported there is doubt about the correctness of the diagnosis.

The diagnosis can not be made till the second stage. The symptoms of the first stage are indistinguishable from those of simple catarrhal jaundice. With the development of the grave symptoms all doubt usually vanishes. The general course of the disease, the deep jaundice, the cerebral disturbances, the cutaneous ecchymoses, and the character of the urine, form a clinical picture resembling no other disease. The only cases where there can be any uncertainty about the diagnosis are the exceptional ones in which there is no jaundice. Acute phosphorus poisoning (*q. v.*) is in many respects very similar in its phenomena, but can generally be differentiated, even if the history of the case is not conclusive. The chief points are that in phosphorus poisoning the liver remains of large size for some time, and is very painful; that the nervous symptoms much less frequently

assume the form of maniacal excitement; and that in but few cases is there any large amount of leucine and tyrosine in the urine.

After what has been said, we need hardly add that **treatment** is unavailing. Usually laxatives are employed, e. g., calomel. The nervous symptoms are combated by an ice-cap and baths and narcotics; the vomiting, by opium and bits of ice; and the cardiac weakness, by stimulants.

## APPENDIX.

### PERNICIOUS JAUNDICE. CHOLÆMIA AND ACHOLIA.

Reference has been repeatedly made in the preceding chapters to the possibility of the sudden supervention of grave nervous derangements in the course of various hepatic diseases. These nervous symptoms resemble one another so much in the different instances of their occurrence that we are forced to believe them always due to the same cause.

These symptoms are relatively most frequent where there is chronic biliary retention. Whether this retention be the result of obstruction of the common or the hepatic duct, or of stenosis of the biliary passages from a carcinoma involving the opening of the common duct into the duodenum, or that duct itself, the patient may quite suddenly fall into a condition which in many respects corresponds to the second stage of acute yellow atrophy just described. Grave cerebral disturbances declare themselves, with delirium, convulsions, and coma. There are hæmorrhages into the skin and into the mucous membranes, and in a few days the patient dies. Usually the end is attended with high fever. We have ourselves seen a temperature of  $107.4^{\circ}$  ( $41.9^{\circ}$  C.) in a case of cancer at the duodenal extremity of the common duct. It is this group of symptoms which is usually termed pernicious jaundice; but almost precisely similar phenomena may suddenly appear in hepatic cirrhosis, when there is no great degree of jaundice, if any.

Just what produces these grave results in acute yellow atrophy and the other disorders just enumerated, we are not certain. Three theories have been propounded in explanation. The first theory, the latest champion of which is Leyden, attributes pernicious jaundice to cholæmia—that is, to the accumulation in the blood of the constituents of bile, and in particular of the biliary acids, as a result of absorption. This accumulation, it is said, is promoted by the paralyzing effect of the jaundice upon the activity of the kidneys. Opposed to this theory is the fact that these same symptoms may occur where there is no marked hepato-genous jaundice.

Traube has suggested that as a result of the great impairment of nutrition there is a cerebral anæmia, which in its turn brings on the nervous attacks. Cohnheim also advocated this view, with some modifications.

The view which we are most inclined to accept is that of Frerichs. He has given to the group of symptoms under discussion the name of acholia. These symptoms he ascribes to the pernicious influence of those substances which under normal conditions are manufactured by the liver into bile, but which in such cases accumulate in the blood and the tissues. As Frerichs himself has said, and we believe very justly, this view should be extended to include all other transforming functions of the liver, and especially the production of urea. It is also very possible that in addition to the acholia, cholæmic poisoning may sometimes exert a simultaneous influence.

The termination of cholæmia or acholia is almost always as unfavorable as that of acute yellow atrophy. In cases of this kind there is usually marked fatty degeneration of the hepatic parenchyma to be found post mortem.

## CHAPTER VII.

## ICTERUS NEONATORUM.

*(Jaundice of the New-born.)*

FREQUENTLY the normal red color of the skin in children changes on the second, third, or fourth day after birth to a distinctly yellow, jaundiced hue. The yellow tinge is deeper on the face and trunk than on the extremities. There are no special digestive or constitutional disturbances. Still it may be taken for the rule that weaklings more often present this jaundice than do vigorous babes. The abnormal hue is almost certain to vanish in a week or two, and leave no sequelæ. The termination is unfavorable in those instances alone where there is some special complication, not directly connected with the jaundice as such.

The ætiology is a disputed matter. A large number of all sorts of theories have been set up, no one of which to this day has gained universal acceptance. Formerly there was considerable tendency to regard the jaundice as hæmatogenous—that is, due to the transformation of the pigment of broken-down blood-corpuscles into bile-pigment. Points which seemed to support this view are the light (not jaundiced) color of the urine and the yellow color of the stools (from bile). But more accurate examination has shown that the urine does contain biliary pigment, as do also the kidneys of such infants as happen to die during the existence of the jaundice; and the biliary acids have been clearly shown to be present in the serous transudations. It may therefore be considered certain that *icterus neonatorum* is hepatogenous; but how the biliary retention and consequent absorption are caused we do not know. Perhaps at first the bile is not ejected properly, from weakness, or the ducts may be narrow, or temporarily plugged by desquamated epithelium. Birch-Hirschfeld has called attention to the fact that after birth there is a tendency to considerable passive congestion of the liver, with resultant œdema of Glisson's capsule and pressure upon the interlobular bile-ducts. We should also consider, as Hofmeier points out, that probably during the first few days of extra-uterine life there is a comparatively large amount of bile secreted, occasioned by the destruction in considerable numbers of the red blood-globules.

It is well to mention in conclusion that in very rare instances there is complete congenital stenosis, or even entire absence, of the larger bile-ducts. Then deep jaundice comes on soon after birth, and is persistent. The children become extremely emaciated, and, after a few weeks, inevitably perish.

## CHAPTER VIII.

## SYPHILIS OF THE LIVER.

**Ætiology and Pathology.**—Syphilitic disease of the liver occurs both when the syphilis is acquired and when it is congenital. Congenital syphilitic disease of the liver may be diffuse or localized, and causes a cellular infiltration in either case. If the changes are extensive, the organ is hard and considerably enlarged; or, if the newly formed connective tissue has undergone contraction, the liver is smaller than normal, and its surface is uneven. In some cases of hereditary syphilis, distinct gummata of considerable size have been observed.

In acquired syphilis, hepatic disease is one of the so-called tertiary symptoms, and does not usually develop, at least to any great extent, until several years after

infection. Indeed, it may be a very late result. It may take the form either of a diffuse syphilitic hepatitis, or of circumscribed gummata or syphilomata. The diffuse hepatitis does not present essentially different anatomical appearances from those of ordinary cirrhosis. The gummata are the most characteristic, and the most important clinically. They may form separate tumors the size of an apple or even larger. The convex surface of the organ, particularly that portion near the suspensory ligament, seems to be a favorite location for the new growth. The same is true of the porta hepatis, where Glisson's capsule enters the liver. At the autopsy the gummata have in most cases already begun to undergo contraction. If so, the liver is usually smaller than normal, and traversed in various directions by deep furrows, which divide it into lobes. These furrows are due to firm cicatricial bands, among the fibers of which we may sometimes find necrotic and cheesy vestiges of the gumma proper. Often there is evident syphilitic endarteritis in the smaller and sometimes also in the larger branches of the hepatic artery and portal vein.

**Clinical History.**—Circumscribed syphilitic changes in the liver often give rise to no symptoms whatever. It is only when the disease comes to disturb the portal circulation that a series of symptoms result, which, for evident reasons, may be analogous in all essential points to the effects of ordinary cirrhosis. Whenever the syphilitic growths contract so as to obliterate a large number of branches of the portal vein, or whenever a gumma happens to be so situated as to compress the trunk of the portal vein itself, then the well-known results of portal obstruction are inevitable, the chief being ascites and enlargement of the spleen. The disturbance of circulation often gives rise also to anorexia and digestive disorders. Experience shows jaundice to be rare in hepatic syphilis, but it may appear when the lesions involve the larger bile-ducts or a considerable number of the smaller biliary passages.

On physical examination, the results vary according to the form and the stage of the disorder. Sometimes the larger gummata may be plainly felt through the abdominal walls, usually as flattened hemispheres. Frequently, also, we can feel the edge of the enlarged organ, and can detect that the edge is less sharp than normal. In other instances the separate elevations and prominences can be made out. The area of dullness on percussion of course varies in different cases.

It deserves mention that hepatic syphilis quite often causes severe pain, sometimes over the entire region of the liver and sometimes in just one spot. Pain is by no means felt in every case. With the pain there may be great tenderness on pressure.

The course of the disease is usually tedious, and may occupy many years. Probably, too, lesions exist in many cases long before there are any symptoms. Just as in cirrhosis, ascites is usually the first thing to attract the patient's attention. Improvement and temporary arrest of the disease are more frequent than in ordinary cirrhosis. Still, in most cases, where the lesions are at all extensive, the termination is unfavorable.

The **diagnosis** is not always easy. Usually the objective changes in the liver, the ascites, and the enlarged spleen, indicate hepatic trouble, but we are often unable to determine just what the trouble is. Naturally, the ætiological factors are of great importance. In a toper we would think rather of the common form of cirrhosis. If there is a syphilitic history, or if we find scars in the throat, irregularities in the surface of the bones, or other signs of a specific dyscrasia, we would naturally ascribe the hepatic disorder to the same cause. As to special signs, if the prominences on the liver are rather large in contrast to the smaller granulations of common cirrhosis, syphilis is somewhat more probable. Severe pain in the right hypochondrium also suggests syphilis rather

than cirrhosis. It should also be considered that the course of hepatic syphilis is usually much more protracted than that of ordinary hepatic cirrhosis.

**Treatment.**—Whether we feel certain that syphilitic hepatitis exists, or merely suspect it, specific treatment should be tried. Mercury and potassic iodide should both be given, but probably the iodide is the more valuable of the two. But these remedies can be successful only when the gummata are still in process of formation. Our therapeutic efforts produce no impression upon the cicatricial bands, the contraction of which is the main cause of derangement. Hence we see why the results of treatment in advanced cases are seldom very favorable.

For symptomatic treatment, the reader is referred to cirrhosis of the liver.

## CHAPTER IX.

### CANCER OF THE LIVER AND BILE-DUCTS.

**Ætiology and Pathology.**—Primary cancer of the liver is very rare, but secondary or metastatic cancer of this organ is met with comparatively often. The chief explanation of this latter fact is the slowness of the blood-current in the liver, which favors the deposition of the cancerous germs suspended in the blood.

Secondary hepatic cancer may be a sequel to primary cancer of any organ. It is most often seen, however, when the primary growth lies within the portal system, in the stomach, intestines, rectum, œsophagus, or pancreas. In some instances the projection of the primary growth into the lumen of a branch of the portal vein has been directly demonstrated, thus furnishing an obvious source for metastasis. The secondary cancers in the liver may be very numerous. They are found both within the organ and upon its surface. If superficial, they form flattened protuberances, which are often dimpled in the middle. If the new growth is extensive, the liver may be greatly enlarged, so as to occupy a great part of the abdominal cavity.

As we have said, primary cancer of the liver is very unusual. It may occur either in the form of separate large nodules, or as a more diffuse cancerous infiltration pervading the greater part of the organ. Histologically considered, the primary growths are of cylindrical-cell carcinoma, apparently originating from the epithelium of the minute bile-ducts, but also, according to some authors, sometimes starting from the cells of the parenchyma.

Primary cancer of the larger bile-ducts is of more frequent occurrence than genuine primary hepatic cancer, and therefore it is of more importance clinically. The gall-bladder may also be the seat of primary carcinoma. From these sources may proceed abundant metastatic growths in the liver itself.

As to the ætiology of hepatic cancer we can be brief. The disease is most frequent in advanced life, from forty to sixty, following in this the general rule for cancer. Special causes are not known. It sometimes seems possible to trace a hereditary predisposition to it. In many cases gall-stones seem to start up the development of carcinoma.

**Clinical History—Diagnosis.**—Many small nodules of cancer, as well as large masses which are favorably situated, may exist in the liver without exciting any symptoms. If there is an undoubted primary cancer in another organ, such as the stomach, we must always remember the possibility of metastatic growths in the liver; but they can not be proved to exist, unless they alter appreciably the size or shape of the organ. Sometimes they may be inferred, when we observe

either ascites and enlargement of the spleen from pressure on the portal vein, or jaundice from pressure on the bile-ducts.

On palpation, we are often able to make out one or more tumors plainly in hepatic cancer. These tumors are in the region of the liver, and they are directly connected with it, as we can prove by marking out its limits by percussion and palpation. Another characteristic sign is that almost all hepatic tumors can be felt to move with respiration, on account of the inspiratory depression of the diaphragm pushing down the liver and all that is joined to it. Percussion over a hepatic tumor almost invariably gives flatness, in contrast to the muffled tympanitic resonance of many gastric tumors.

The most characteristic condition is not a very rare one; in it the liver is the seat of a very large number of cancerous nodules. In such cases the organ is usually much enlarged. Often we can detect by mere inspection a great, irregular prominence in the hepatic region, pressing forward the flabby, atrophied walls of the abdomen, and reaching down to the level of the umbilicus, or even lower. On palpation, we can feel most of the anterior surface of the liver, and the separate cancerous nodules scattered over it. These usually are as large as walnuts, or even apples. The lower or anterior margin of the liver can often be made out plainly, and it also is often the seat of nodules; and we can sometimes feel nodules on the lower surface of the organ.

The other clinical phenomena in hepatic cancer have several causes: (1) The primary disease, such as cancer of the stomach; (2) the general cancerous cachexia, as shown by languor, emaciation, and possibly a slight oedema of the ankles; and (3) the possible compression of the blood-vessels or bile-ducts. This compression is not infrequent, and produces a moderate or even a large ascitic effusion. Even in these instances the spleen is seldom much enlarged as a result of the passive congestion, because the universal emaciation and anæmia counteract the tendency to increase in size. Jaundice is relatively more frequent in cancer of the liver than in ascites. It is caused by compression either of the hepatic duct or of the minuter bile-ducts. On the other hand, however, we can easily see that hepatic cancer may exist without producing either icterus or ascites.

The differential diagnosis of hepatic cancer from cancer in other organs is sometimes extremely difficult. This is particularly true of pyloric cancer, and especially so when the pylorus has become adherent to the liver, which often is the case. Cancers of the omentum and of the colon sometimes simulate hepatic cancer, but they seldom move so decidedly in respiration as do hepatic tumors. Given a new growth in the liver, it is usually comparatively easy to distinguish between carcinoma and other tumors. The benign growths, like adenoma, are so rarely found in the liver that they can actually be almost disregarded. If there are syphilitic growths, we may be aided by the history of the case and other signs of syphilis, or by the eventual contraction and atrophy of the organ. Echinococci have, as a rule, a much more regular shape, like a flattened sphere. Large abscesses are rare in our latitudes; and if they occur, usually the aetiology is significant. They also frequently cause fever and rigors, which cancer does not.

When we have decided that cancer of the liver is present, the question arises, Is it primary or secondary? In the first place, primary cancer here is so rare that the probabilities are in favor of a secondary growth. Not infrequently the primary tumor can not be detected during life. Thus a small cancer of the stomach, or a flat oesophageal cancer, or carcinoma of the pancreas, are all easily overlooked. If we find many nodules in the liver and no primary trouble elsewhere, then there comes the possibility that there is primary cancer in the gall-bladder or the bile ducts. In rare instances palpation may discover the gall-

bladder in a state of cancerous degeneration close underneath the liver; but usually the viscus will be small and contracted, and the flat and ulcerating growth is not noticeable, except from the inside. It is particularly in those cases of hepatic cancer where there is great and persistent icterus, and no evidence of carcinoma in any other organ, that we should be most apt to think of primary cancer of the bile-ducts.

The duration of hepatic cancer is usually not prolonged. The first decided evidences of its existence no sooner present themselves than marasmus and cachexia rapidly develop. The fatal end comes in a few months, or at latest within a year.

The prognosis is hopeless. Treatment can avail only to alleviate somewhat the patient's sufferings.

## CHAPTER X.

### ECHINOCOCCUS OF THE LIVER.

**Natural History and Pathology.**—Inasmuch as it is the liver which suffers most frequently from invasions of the echinococcus, we will here state the main general points relative to the troubles produced by this parasite.

The *tenia echinococcus* (see Fig. 53) is a small tape-worm about four millimetres long, and composed of three or four joints. It inhabits the intestinal canal of the dog. Man becomes infected by the ingestion of the eggs of this tape-worm into the stomach. The striking prevalence of the disease in Iceland is explained by the fact that the inhabitants live in constant contact with their numerous canine friends. Among us the echinococcus is comparatively rare.

If a human being has become infected, the blood-current carries the embryo into some organ. In a great majority of cases it passes through a branch of the portal vein into the liver and there fastens itself; but the echinococcus may be developed in other organs—like the lungs (*vide* page 252), the bones, the brain, and the kidneys. A hydatid cyst develops from the embryo, and is filled with a non-albuminous fluid. The cyst is composed of an external cuticle of lamellated structure, and an inner, parenchymatous layer, which contains muscular fibers and blood-vessels. Surrounding the cyst, as it lies in the infested organ, there is gradually developed a thick capsule of connective tissue.

After the cyst has continued its growth for some four to six months, being now about the size of a walnut, there are generated upon the inner surface of the capsule, from the parenchymatous layer, so-called breeding capsules, containing numbers of echinococcus-heads, or "*scolices*." Each scolex has four suckers and a circle of hooks. It can draw itself into the breeding capsule and also produce a prominence upon the outer surface of the latter (see Figs. 54, 55, and 56).

Usually the primary cyst gives rise to secondary "daughter vesicles," and these to "granddaughter vesicles." Some of these are formed in the cuticle, others from the breeding capsules. In man they generally grow inward—that is, are

cus, of natural size.

endogenous (*echinococcus hydatidosus*)—and finally become detached. Hundreds of them may sometimes be found free in the liquid contents of the cyst. In animals the daughter vesicles are more often exogenous (*echinococcus veterinorum seu granulosis*). A peculiar kind of echinococcus, which was formerly regarded as a kind of new growth, is that called by Virchow *echinococcus multi-*

FIG. 54.

FIG. 56.—*Echinococcus* booklets.

*locularis*. This gives rise to a hard tumor, which is composed of vesicles the size of a pea, and which seems to grow along the lymph-vessels, and possibly in the blood-vessels also.

The growth of a hydatid cyst is slow, and may continue for years. It may finally attain the size of a child's head. At last, however, the echinococcus dies. The cyst then undergoes considerable though gradual contraction, and both walls and contents become calcified.

**Clinical Phenomena.**—As long as the cyst in the liver retains moderate dimensions, there is usually no discomfort. Frequently the cysts perish and become calcified, without having ever attracted attention, and are found post-mortem merely by accident.

If the cyst becomes very large, it causes a sensation of pressure and pain in the hepatic region. In rare instances, unusually large cysts, if situated on the convex surface of the liver may crowd up the diaphragm so as to compress the lower portions of the lung and induce dyspnoea. Again, the cyst may be so situated as to compress the portal vein or a large bile-duct. Then appear ascites and enlargement of the spleen, or jaundice, as the case may be.

It is an important fact that sometimes the cyst ruptures and discharges its contents into neighboring parts. Thus in repeated instances the pleural cavity has been invaded; also the lungs, as evidenced by the expectoration of vesicles; the intestinal canal, with the appearance of vesicles in the stools; the bile-ducts, followed by jaundice and the eventual appearance of vesicles in the intestine; and the vena cava inferior, causing sudden death from pulmonary embolism. Sometimes the cyst pushes outward through the abdominal walls, and terminates in recovery. Exceptionally, the echinococcus sac undergoes purulent inflammation, with all the symptoms of a hepatic abscess.

A multilocular echinococcus usually excites grave disturbance. The liver is decidedly enlarged, and generally is firm and smooth, not uneven, to the touch. As a rule, there are jaundice, swelling of the spleen, and ascites, and accompanying these a gradual loss of flesh and strength, ending fatally.

A diagnosis is sometimes easily reached if the cysts can be felt upon the surface of the liver. Usually the tumors are flat or globular, and of firm consistence, though often evidently elastic. A peculiarly characteristic sign, though one which is seldom obtainable, is the "hydatid thrill." It is felt upon giving the tumor a quick, short blow with the flat of the hand. The diagnosis is certain if, in any way, echinococcus vesicles are discharged. Aspiration for purposes of diagnosis

has been repeatedly performed. The fluid thus evacuated is light-yellow, almost always non-albuminous, and, upon microscopic examination, sometimes presents fragments of the lamellated membrane, or some of the hooklets. But if we do not find these morphological elements, we are by no means warranted in excluding echinococcus. Chemically, the fluid should yield sugar and succinic acid. This fact may perhaps aid diagnosis.

Frequently it is difficult to distinguish between an echinococcus of the liver and other hepatic disorders. We may need to consider all the circumstances—causation, age, fever, shape of the tumor, or perhaps the results of an exploratory puncture. Large cysts, which crowd themselves upward into the pleural cavity may simulate a pleuritic effusion.

**Treatment.**—The administration of internal remedies is extremely unreliable. Iodide of potassium and mercury are especially recommended. It is, however, operative interference alone that holds out any promise of success; but this has its dangers, and should, therefore, be held in reserve till the symptoms become grave or very distressing. For details of the numberless methods of operation which have been proposed, we would refer to works on surgery; but we may mention here that simple aspiration of the contents of the cyst sometimes affords permanent relief; the cyst becomes obliterated, and there is complete recovery. In a few cases, after the sac has been emptied, tincture of iodine has been injected. Most of the other methods aim (1) to bring about adhesion of the sac to the abdominal walls, and (2) to lay it open and evacuate the contents. At the surgical clinique in Leipsic the favorite and a very satisfactory method is to employ a caustic paste, made with chloride of zinc, which slowly effects an opening of the cyst, and, by the adhesive inflammation it excites previously, fixes the cyst to the abdominal walls. Simon's method is to thrust in several trocars, at intervals from one another, and allow them to remain till adhesions are formed. Then the points of puncture are united by an incision, the sac emptied, syringed out, disinfected, and allowed to heal gradually.

[The experience of Australian surgeons with hydatid disease is very large, and Thomas believes that the cure, after tapping, is often illusory, and that failure follows in at least forty per cent. of the cases. He has collected sixty-eight cases of hydatid diseases treated by laparotomy, with only seven deaths. In twenty-one cases treated as in Leipsic (Volkmann's method), the mortality has been nineteen per cent.]

## CHAPTER XI.

### CIRCULATORY DISTURBANCES IN THE LIVER.

1. HEPATIC anæmia is seldom extreme except in cases of profound general anæmia, and has no clinical importance, so far as we are aware.

2. Passive congestion of the liver is of frequent occurrence and is of importance. It may arise in any disorder which disturbs the systemic circulation. It is oftenest seen in connection with heart disease, particularly mitral disease. It also follows pulmonary emphysema and chronic processes which result in contraction of the lungs. The liver is enlarged and engorged. The hepatic veins being situated in the center of the lobules, this central portion becomes darkly pigmented, while the periphery of the lobules seems lighter colored. The peripheral cells may even appear distinctly yellow, from a fatty infiltration which is not infrequent. In this way the cut surface comes to present that variegated appearance which has led to the name of "nutmeg liver." If the venous stasis be per-

sistent, there is considerable atrophy of the hepatic parenchyma, involving especially the cells near the center of each lobule. Thus the liver atrophies, and its surface may become slightly granular. This is the "atrophic nutmeg liver."

The clinical phenomena are chiefly those due to the hepatic enlargement. If chronic cardiac disease, emphysema, or some analogous trouble has occasioned congestion of the liver, the area of hepatic dullness is increased, and frequently we can feel the edge or even a portion of the anterior surface. In pronounced cases the organ may extend almost a hand's breadth below the ribs. Often there is a slight jaundice. Sometimes it is quite marked. It is probably due to the distended blood-vessels compressing the smaller bile-ducts. We have already mentioned how characteristic, in many cardiac cases, is a complexion presenting both cyanosis and jaundice.

Quite often the congestion, if great, produces subjective disturbances. There is a feeling of pressure and weight in the hepatic region; and if the capsule of the organ is tightly stretched, there may be actual pain.

The prognosis and treatment depend, of course, upon the primary disorder.

3. About active hyperæmia of the liver we have little definite information. Formerly there was a great deal said about it, as one of the conditions in "abdominal plethora." Active hyperæmia is most frequently assumed to exist in case of those who are good livers and of sedentary habit. In such, we are told, the temporary physiological hyperæmia which attends digestion passes on into a permanent congestion of the liver. Thereby the organ is enlarged, there are painful sensations in the right hypochondrium, digestive disturbances, and occasional slight jaundice. The abnormal condition just described is certainly often met with in practice, but it would seem hardly possible to draw a clear dividing-line between active hyperæmia of the liver and other disturbances which give rise to similar symptoms. Such are chronic gastric and intestinal catarrhs; cardiac hypertrophy and functional cardiac derangement, with passive congestion of the liver; fatty liver; and incipient cirrhosis.

A prominent factor in the production of active hyperæmia of the liver is also ascribed to the ingestion of such matters as are said to "irritate" the liver, like the various spices, coffee, and, above all, alcohol.

It should also be noted that the liver may be much engorged in many acute infectious diseases, particularly in pernicious malarial diseases and in typhus or typhoid fever.

It is also maintained that the hyperæmia may result from the cessation of hæmorrhages elsewhere, such as the catamenia or bleeding from hæmorrhoids. The facts that have been brought forward to sustain this view are none of them conclusive. We will mention that the "menstrual jaundice" which occasionally appears when the menses are scanty or absent has been referred to a vicarious hyperæmia of the liver.

It is, of course, impossible to make general statements about the course and duration of active hyperæmia of the liver. The treatment of the first variety mentioned—namely, that arising from an improper mode of life—demands careful regulation of the diet, abundant exercise in the open air, like horseback-riding, and laxatives. We may give rhubarb, aloes, or a course of the waters at Carlsbad, Marienbad, Kissingen, or Homburg.

## CHAPTER XII.

**ATROPHY, HYPERTROPHY, AND DEGENERATIONS OF THE LIVER.**

1. **Simple Atrophy of the Liver.**—Simple atrophy is not of rare occurrence, being seen in senile marasmus, and in malnutrition from almost any cause. The degree of atrophy varies. The borders of the organ are much wrinkled. The lobules seem decidedly smaller than normal, and even the individual cells that still remain are atrophied and also usually deeply pigmented.

The condition does not of itself give rise to any special symptoms. The area of hepatic dullness is usually lessened, but this sign is too ambiguous ever to justify us in making from it a diagnosis of hepatic atrophy. Perhaps there is some value in the alleged lighter color of the stools, as indicating a diminished secretion of bile.

2. **Hypertrophy of the Liver.**—Even under normal circumstances the liver undergoes quite marked alterations in size. The exact point, therefore, where an abnormal hypertrophy begins can not be set. Sometimes the autopsy reveals an unusually large liver, of which there had been no indications during life, and for which no cause can be made out.

There are certain diseases in which enlargement of the liver is found with comparative frequency: diabetes mellitus, chronic malarial poisoning, leukaemia, and sometimes rachitis. Topers quite often have enlarged livers, which as a rule present simple hypertrophic changes. Occasionally a liver has been reported as showing spots of localized hyperplasia, which may form flattened prominences upon the surface of the organ.

Hypertrophy is to be diagnosticated only when palpation and percussion give proof of an enlargement, and yet amyloid, hypertrophic cirrhosis, and other diseases which cause an increase in the size of the liver, can be excluded. The etiology of the case should also be considered.

3. **Fatty Liver.**—This name is applied to excessive, diffuse, fatty infiltration of the hepatic cells. The size of the organ is increased. It is firm, anæmic, and of a uniform yellow color, both externally and upon section. The microscope shows that the cells of the parenchyma are filled with large and small globules of fat. The fat is most abundant toward the periphery of the lobules.

The causes of fatty liver are by no means clear. Sometimes it is found in cases of general obesity, where we may assume that the amount of fat which the liver receives as nourishment is abnormally great; but often we find a liver that contains comparatively little fat in those who have a well-developed panniculus adiposus and much fat in other organs. Topers may have a decidedly fatty liver. The occurrence of fatty liver in the cachectic, and particularly in the consumptive, is remarkable; and individuals suffering from cancer, or marantic children, may also exhibit the same change. We have no intimate knowledge of the conditions that prevent, in such cases, the oxygenation of the fat which comes to the liver from the ingesta or from other organs.

We do not know that the fatty liver is in any way functionally impaired. The only clinical indication, therefore, of its existence is the increased bulk of the organ. In phthisis we may sometimes feel pretty certain that the liver is fatty, if an increase in bulk can be demonstrated, and if other causes for this enlargement, like amyloid, appear improbable. If the anterior edge of a fatty liver can be felt, it is usually found to be noticeably thick and blunt.

The treatment of fatty liver is to combat the original disease.

4. **Amyloid Liver (Waxy Liver).**—Amyloid degeneration of the liver is almost invariably a part of extensive amyloid disease, involving also the spleen, kidneys,

intestine, and other organs. The disease occurs chiefly in certain cachectic conditions, such as chronic suppuration, as in caries and persistent empyema, and also in chronic pulmonary tuberculosis, and constitutional syphilis.

The amyloid liver is usually increased in bulk. The organ may even become almost double its normal size. It feels very firm and hard, its surface is perfectly smooth, and its edge is slightly thickened. The cut surface presents a characteristic grayish-brown "waxy" appearance.

The microscope shows that the degenerative process attacks chiefly the walls of the hepatic capillaries, the hepatic cells proper showing infrequent and slight amyloid changes. Very often the cells of the parenchyma are atrophied and somewhat infiltrated with fat.

The diagnosis of amyloid liver requires (1) the demonstration by palpation and percussion of hepatic enlargement. We can often feel a large part of the anterior surface and the margin of the hard and firm organ. The liver may reach as low as the level of the umbilicus. The diagnosis further demands (2) that some disease which predisposes to amyloid be present, and (3) that there be evidence of the degenerative process in other organs: the spleen should be enlarged, and the kidneys secrete albuminous urine.

The other symptoms, as well as both prognosis and treatment, are determined mainly by the nature of the causative affection. About amyloid disease in general see the chapter on amyloid kidney (page 864).

### CHAPTER XIII.

#### ANOMALIES IN THE SHAPE AND POSITION OF THE LIVER.

**1. Corset Liver.**—The constant pressure of the lower ribs against the liver, as a result of tight lacing, often produces an atrophy of the hepatic parenchyma from pressure, as shown by a deep furrow crossing transversely the anterior surface of the organ. This "corset furrow" lies chiefly in the right lobe. Its usual situation corresponds to the margin of the ribs, and the atrophy may be so extreme that the liver is divided into a large upper part and a small, usually roundish, lower portion, connected by a narrow isthmus of tissue. At the atrophic place, the connective-tissue capsule of the liver is almost always much thickened. Often the lower section can be bent upward as if attached by a hinge.

This deformity of the liver is found quite often in elderly females, and rarely in men, as in soldiers. Unless extreme, it can not be detected during life, and causes no discomfort. Even the bad cases do not, as a rule, occasion any special symptoms; but they can be clearly made out if the abdominal walls are lax. The deep transverse furrow can be felt, and also the lower section, with its usually blunt edge. Particularly in the case of old women we must bear this condition in mind, else we might easily confound it with some enlargement of the liver, like amyloid or passive congestion, or even new growths.

In not rare instances there are clinical symptoms. A constant sensation of pressure and pulling is felt in the hepatic region; and sometimes, as a result of venous stasis, there is a temporary but decided swelling of the isolated portion, and possibly violent pain and indications of irritation of the peritoneum, such as vomiting and an approach to collapse. Usually rest in bed and cold applications give speedy relief; but relapses are possible.

**2. Movable Liver.**—A movable or "wandering" liver is of very rare occurrence, and has thus far been seen only in women. Its cause is not perfectly deter-

mined. Probably the suspensory ligament is abnormally long. The liver does not occupy its usual position, but lies deep in the lower part of the abdomen. Here it can be plainly felt, and, by external pressure, it can generally be brought back into its normal place with considerable ease. It is always abnormally movable, and can be shown to change its position when the patient changes from one side to the other.

In most cases a movable liver causes considerable discomfort, particularly pain and digestive disturbances. The only way of affording relief is by applying a bandage which may maintain the organ in its proper position.

#### CHAPTER XIV.

##### SUPPURATIVE PYLEPHLEBITIS.

*(Purulent Inflammation of the Portal Vein and its Branches.)*

**Etiology.**—Purulent pylephlebitis is seldom a primary, idiopathic disease. In most instances it is due to the propagation of a suppurative inflammation of neighboring tissues to the walls of the vein. The main trunk of the portal vein is rarely directly attacked. Usually the process originates in the hepatic branches of the vein or in the veins of the portal system, and thence extends to the larger vessel.

Perityphlitic abscess is the most frequent source of suppurative pylephlebitis. The inflammation involves a mesenteric vein, and thence extends upward. Other causes are gastric ulcer, intestinal ulcers, as in dysentery, splenic abscess, and purulent inflammation at the porta hepatis or within the liver itself, as in abscess due to gall-stones. The mode of production in these cases is precisely analogous to that in perityphlitic abscess; but they are rare.

A special form of pylephlebitis is observed in the new-born. Here the inflammation originates in the umbilical vein, and we need hardly say that the cause is a septic infection through the navel.

In rare instances it has been found that pylephlebitis has resulted from the penetration into a vein of some foreign body that had been swallowed, such as a pin. Here, too, the true factors in producing the inflammation are, of course, the bacteria which adhere to the foreign body.

**Pathology.**—Where the inflammation has attacked the vascular walls, the vein is thickened, and often the surrounding connective tissue is infiltrated with pus-cells and mottled with minute ecchymoses. If the vein is cut open, the intima is seen to be opaque and often superficially ulcerated. The lumen of the vessel is filled with a thrombus, which is usually to a great extent in a state of purulent softening, so that offensive purulent or sanious fluid flows out. The course of events is as follows: First, the wall of the vein becomes inflamed. As a consequence of this, a thrombus forms at the same place. The bacteria penetrate this thrombus and occasion its purulent softening.

The extent of a pylephlebitis naturally varies in different cases. As a rule, little fragments become detached from the thrombus and enter the liver, producing metastatic abscesses. Secondary suppuration may also occur in the lungs, kidneys, brain, and joints, so that we have all the anatomical characteristics of a general pyæmia.

**Clinical History.**—Inasmuch as the primary, causative disease may be very different in different cases, it is impossible to delineate the disease comprehen-

sively. It is, however, frequently ushered in by a number of symptoms, which render a diagnosis possible, at least in some cases, if the original disease has been recognized.

The symptoms of suppurative pylephlebitis are in part due directly to the local disease itself, and in part are occasioned by the general pyæmia. One of the local symptoms is pain in the epigastrium. This is rare. It may radiate downward or laterally, according to the starting-place and extent of the inflammation. An inevitable result of the portal thrombosis is portal obstruction. The spleen becomes considerably swollen, and, if the disease be not too quickly fatal, there is an evident effusion into the peritoneal cavity. The splenic enlargement can not be regarded as due merely to venous stasis, but is in part the "acute splenic tumor" of constitutional septic conditions. If the inflammation spreads from the branches of the portal vein to the neighboring bile-ducts, jaundice results. This is seen quite often. Sometimes it is also due to the hepatic abscesses, or to a gall-stone which happens to cause trouble simultaneously. Now and then there is no jaundice whatever.

Of the pyæmic symptoms, hepatic abscesses come first. They are due, as we have said, to the conveyance of septic matter directly into the liver by emboli. The one almost constant sign of their occurrence is a decided enlargement of the liver. Where there are no hepatic abscesses, the organ usually retains its normal bulk.

The course of the fever is very characteristic. As in other pyæmic conditions, there are almost invariably great elevations, to  $106^{\circ}$  ( $41^{\circ}$  C.), or higher, accompanied by rigors, and followed by marked remissions, with profuse perspiration. These onsets of fever occur at irregular intervals, either daily, or every two or three days.

There are at the same time indications of constitutional septic infection, which keep increasing in severity. The pulse grows rapid and small. Intelligence is impaired. Somnolence and delirium come on, and the strength rapidly fails.

There are other symptoms. Vomiting is frequently seen. The bowels are seldom constipated, but usually relaxed. The dejections may contain blood, because of the venous stasis. In some cases the inflammation extends so as to produce a fatal general peritonitis. It is noticeable that the urine is generally scanty, and the amount of urea is strikingly diminished.

The disease usually runs a rather acute course. On the average, it lasts about two weeks, but may occupy three or four weeks, or even a longer period. It is invariably fatal. At least, no cases of recovery are known.

The diagnosis can sometimes be made with considerable positiveness. In other instances it is impossible to exclude other pyæmic conditions, or abscess due to gall-stones, etc. Important factors are the origin of the trouble—if it can be made out—the pyæmic rigors, the enlargement of the spleen and liver, jaundice, epigastric pain, and the evidences of general sepsis.

Treatment is unfortunately almost entirely useless. The fever is not affected even by large doses of quinine. All we can aim at is to support and relieve the sufferer as far as possible.

## CHAPTER XV.

## THROMBOSIS OF THE PORTAL VEIN.

*(Chronic Adhesive Pylephlebitis. Pylethrombosis.)*

**Ætiology and Pathology.**—Like suppurative pylephlebitis, chronic portal thrombosis is not an independent disease, but is the sequel of a great variety of pathological conditions. Marantic thrombosis is of rare occurrence, and is usually formed toward the close of life, so as not to be of practical interest. Apart from this, almost all cases of thrombosis of the portal vein are due to a compression of the trunk of that vessel or one of its main branches. This most often occurs in certain chronic hepatic diseases which involve a mechanical stenosis, either of the smaller branches of the portal vein within the liver, or of the vein itself, with resulting coagulation of the blood within it. Chief among these diseases are cirrhosis and syphilis of the liver, which have repeatedly been observed to entail portal thrombosis; but other diseases in the neighborhood of the vein may produce a similar effect. New growths of various kinds may press upon the vessel, or chronic inflammatory hyperplasia of the connective tissue at the porta hepatis may act in the same way. This is illustrated in chronic peritonitis, whether circumscribed or diffuse, an example of the former being sometimes seen as an effect of duodenal ulcer.

It was formerly held that many forms of so-called "lobulated liver" were due to a primary adhesive pylephlebitis. This is erroneous. These cases are probably all due to some primary hepatic disease, usually syphilitic. The size of the liver is little influenced by obstruction of the portal vein, even if long continued, for the hepatic artery suffices to supply all the blood required by the organ.

The anatomical changes in pylethrombosis do not differ essentially from those seen in thrombosis of any other vein. If fresh, the thrombus is still red; later it grows harder, paler, and more friable. If the thrombosis has existed a long while, the clot becomes completely organized. We have observed this even in the main trunk of the portal vein.

**Clinical History.**—The symptoms of portal thrombosis are those occasioned by the obstruction, and therefore such as we have already repeatedly met with, in connection with various hepatic diseases. The intensity and extent of these results, as well as the time occupied in their development, depend, of course, upon the place and size of the clot. If it is the portal vein itself which is attacked, and if the thrombus is extensive enough to obstruct the flow of blood, then the signs of venous stasis are evident throughout the portal system. The spleen becomes much enlarged, as can be easily demonstrated by percussion and palpation. Soon ascites appears, as a result of the passive congestion of the peritoneal veins; and from a similar condition of the gastro-intestinal veins arise catarrhal disorders, like diarrhoea; or, not so very exceptionally, there is repeated gastric and intestinal hæmorrhage.

As we have seen, a collateral circulation may be developed (*vide* page 481), by which the venous blood of the portal system is enabled to reach the systemic veins. This explains why some of the symptoms of venous stasis may temporarily (perhaps permanently) vanish. We saw one case of portal thrombosis, the sequel to what was apparently a syphilitic disease of the liver, where a quite large ascitic effusion appeared some six or seven times at intervals of three to six months, and under proper treatment as often abated. The patient did not die till the illness had lasted six years, and tapping had been demanded some fifteen times. At the autopsy the trunk of the portal vein was found to be converted into a fibrous cord, with a lumen which barely admitted a knitting-needle. It is the develop-

ment of a collateral circulation which causes the frequent distention of the veins in the abdominal walls. Sometimes these enlarged veins take the form of the "*caput Medusæ*" mentioned above.

In simple pylethrombosis there are no local symptoms such as pain. The condition of the liver depends upon the primary disease. It is possible that a moderate atrophy of the entire organ might at length ensue if the portal blood were permanently cut off from it. But, as we have said, any cirrhotic changes, or any "lobulation," are not to be regarded as the result, but as the cause of the thrombosis, or at least related to the cause.

The course and duration of the trouble are according to the nature of the original, causative trouble. No general statements can be made.

The diagnosis of thrombosis of the portal vein is usually extremely difficult, and can really hardly ever be made with absolute certainty. We may, indeed, recognize readily that there is some decided obstruction to the portal circulation; but whether this be due to a thrombus, or to compression of the portal vein, or to the obliteration of a large number of the smaller branches of that vein within the liver, we can very seldom determine. Pylethrombosis may be regarded as probable, if no other possible cause of the portal obstruction seems likely, and if we are able to discover a cause for thrombosis, like a former attack of circumscribed peritonitis.

The prognosis is always unfavorable, although there may be, as we have said, great temporary improvement. Treatment must be symptomatic, and follows in the main the principles set forth under cirrhosis of the liver.

## APPENDIX.

### DISEASES OF THE PANCREAS.

THE few facts of clinical importance that are known about the pathology of the pancreas are given below.

1. **Hæmorrhages into the Pancreas** of small size occur as one symptom of a general hæmorrhagic diathesis, or as the result of excessive passive congestion. They are of no special importance. Klebs and Zenker have described a few cases, however, where there was extensive hæmorrhage into this organ, and where this was the only discoverable cause of death. The patients had been previously well and vigorous, although decidedly obese, and had died suddenly. Perhaps the speedy termination was caused by the influence of the hæmorrhage upon the semilunar ganglion or solar plexus. The cause of the hæmorrhage could not be determined.

2. **Atrophy of the Pancreas.**—The organ may share in a general marasmus. There is also extreme atrophy of the pancreas in those who have died of diabetes mellitus (*q. v.*). What relation this change bears to the diabetes is not known.

3. **Pancreatitis.**—A few cases have been reported of what would seem to be a primary acute pancreatitis. The disease is certainly very rare. It begins with violent colicky pains in the epigastrium. Vomiting and collapse soon follow. The pulse grows small, the extremities become cool, and death is speedy. At the autopsy the pancreas is found to be much enlarged, and mottled with ecchymoses, or it even presents scattered foci of suppuration. The ætiology is unknown. Secondary abscesses of the pancreas are not infrequent in pyæmia.

[Fitz, in the Middleton-Goldsmith lecture for 1889, threw much light on the ætiology and diagnosis of acute pancreatitis, which he subdivides into three anatomical forms—the hæmorrhagic, the suppurative, and the gangrenous. He shows

that the affection is not so rare as has been supposed; that its victims are usually in middle life, fat, and good livers; that it commonly originates by the extension of a gastro-duodenal inflammation along the pancreatic duct.

"If the case does not end fatally in the course of a few days, recovery is possible, or a recurrence of the symptoms in a milder form takes place, and the characteristics of a subacute peritonitis are developed."

In the differential diagnosis irritant poisoning, perforation of the digestive or biliary tracts, and acute intestinal obstruction are to be considered. The location of peritonitic symptoms, their suddenness of onset, the absence of apparently sufficient cause, and the age and habit of the individual are important points.]

Chronic interstitial pancreatitis sometimes results from the extension of chronic inflammatory processes affecting neighboring parts. Friedreich states that it sometimes is a primary disease in toppers. Syphilitic lesions of the pancreas have been observed, occasioning contraction and induration. None of these changes give rise to special clinical symptoms; or, if there were a single distinctive symptom, it would be one common to all sorts of grave pancreatic disorder—namely, the appearance of a large amount of fat in the stools. As we know, the pancreatic juice is an important factor in the digestion of fat, so that it is very natural for any great derangement of the organ to have this result; and yet the bile alone may render the ingested fat capable of absorption, so that in repeated instances there have been no fatty stools when the pancreas has been completely atrophied or degenerated.

**4. Cysts of the Pancreas.**—After closure of Wirsung's duct by scars, concretions, or the like, cysts of the pancreas may form, as a result of the damming up of the secretion. These may become so large as to be felt as great tumors through the abdominal walls. In some instances they have been operated upon with success.

**5. Cancer of the Pancreas.**—Primary cancer is the most frequent, and therefore clinically the most important disease of this organ. As a rule, the new growth is situated in the head of the pancreas. It is usually of the medullary variety, though occasionally colloid. It may involve neighboring parts by direct extension, and a great many organs by metastasis; for example, the liver, peritoneum, and lymph-glands.

The clinical symptoms of cancer of the pancreas are very seldom so decided as to justify a positive diagnosis. Sometimes the secondary nodules can be detected in the liver, peritoneum, and elsewhere. Then we are left in doubt about the seat of the primary growth. Or the primary tumor may be plainly felt through the abdominal walls; but then we can hardly ever exclude cancer of the stomach or of the omentum, and neighboring parts.

The symptoms of pancreatic cancer, as a whole, resemble closely those occasioned by most cancers of abdominal organs. Usually the patient is elderly. The first symptoms are loss of flesh and strength, or are the result of compression. Often there is complaint of a persistent dull pain in the epigastrium. If the portal vein is pressed upon by the tumor, ascites appears. If the common duct is compressed, there is jaundice. Marasmus increases, and usually at the end of six months or a year the patient dies.

The diagnosis can be said to be somewhat probable in those cases only where there are fatty stools, where a tumor can be felt in a position corresponding to the pancreas, and where primary cancer of any other organ is unlikely; but usually, as we have said, the symptoms are very ambiguous. There have been no fatty stools in a number of cases, even where the cancer was extensive.

The prognosis is absolutely bad. The treatment is merely symptomatic, with the aim of lessening the patient's suffering.

## DISEASES OF THE NERVOUS SYSTEM.

### I.—The Diseases of the Peripheral Nerves.

#### SECTION I.

##### *DISEASES OF THE SENSORY NERVES.*

#### CHAPTER I.

##### **GENERAL REMARKS UPON THE DISTURBANCES OF SENSIBILITY.**

THE disturbances of sensibility, like all other functions of the nerves, are manifested in two directions. Under pathological conditions we observe either an abnormal diminution or a complete absence of sensibility—anaesthesia—or a morbid increase—hyperaesthesia. While, in anaesthesia, the ordinary or even the strongest irritations which excite the sensory nerves produce only a weak and insignificant sensation, or even no corresponding sensation at all, in hyperaesthesia very severe and painful sensations are caused by weak irritations. The "symptoms of sensory irritation" are to be distinguished from hyperaesthesia, although they are often present along with it. By this term we mean sensations which cause internal irritation, not from without, but from certain abnormal morbid conditions in the nerve itself. In the region of cutaneous sensibility, with which we shall chiefly concern ourselves in what follows, these symptoms of sensory irritation show themselves partly as actual pain and partly as the so-called paræsthesiæ—that is, abnormal sensations in the skin, which are termed "formication" (the crawling of ants), "prickling," "numbness," "a furry feeling," etc.

**The Different Varieties of Cutaneous Sensibility and the Methods of testing them.**—As is known from physiology, the irritation of the sensory cutaneous nerves produces in us a number of sensations, differing in quality according to the manner of action of the irritation. If, therefore, we would obtain an accurate estimate of the condition of the patient's cutaneous sensibility, we must make a special test of all the different forms of sensation, for we often see that the disturbances of sensibility do not involve all the forms mentioned alike, but that one kind of irritation is followed by perfectly normal sensations, while there is more or less complete anaesthesia for another kind. We term such partial anaesthesias of the skin, which are manifest toward only one form of irritation, "partial paralysis of sensation." Such partial paralyses will be much more easily understood if the remarkable statements of Blix, Goldscheider, and others are confirmed. According to these statements, the different qualities of cutaneous sensation are transmitted to the consciousness by special nerve-fibers, so that there are in the skin special nerves for the tactile sense, for the sense of cold, for the sense of heat, etc. Such a condition is analogous to the well-known specific energy of the different fibers of the optic nerve to colors, assumed by many physiologists. The

separate varieties of cutaneous sensibility, and the methods of testing them, are as follows:

1. **TACTILE SENSIBILITY.**—The examination of the tactile sensibility—that is, of the sensibility of the skin to simple contact—is usually performed by repeatedly touching or stroking the part of the skin to be tested with the finger, a fine brush, or some other blunt object (not of metal, in order to exclude sensations of cold) while the patient's eyes are shut, and making the patient say whether he has felt the touch or not. When it is necessary to call the patient's attention to the investigation, it is always best to do so afresh by asking "Now?" and then either really touching the skin or else asking the question when only pretending to do so. In this way we are safest from error, which is otherwise easily produced by a lack of attention or of practice on the part of the patient. All accurate tests of sensibility must be repeatedly performed and controlled in order to obtain accurate objective results.

If, as in most cases, we have to do with disturbances of sensibility which affect only a part of the skin, we must make comparative tests of sensibility on the healthy and, if possible, symmetrical portions of the skin. Slight disturbances of sensibility are then often shown in this way, that the patient feels almost every touch on the affected part; but the sensation always seems to him more indefinite, blunter—in short, "different" from that on the corresponding normal portion of the body.

Besides simply touching the skin, we also try how far the patient is able to distinguish the form and certain external peculiarities of objects by the aid of his tactile sense. We touch the skin with smooth and rough (woolly) or round and angular objects, and see whether the patient can distinguish them respectively with his eyes shut, and also whether he can distinguish between the head and the point of a pin, etc. If we are testing the sensibility of the fingers, we may put different well-known objects—like coins, rings, or keys—into his hands, and let him name them with his eyes shut. We may also try the last method of testing by the aid of a number of wooden geometrical objects, cubes, octahedra, or cones.

2. **SENSE OF LOCALITY.**—Under normal conditions, as we know, not only do we feel the touch of an object, but we can tell with a good deal of accuracy the place on our skin which was touched. This power we term the ability to localize our sensation. In nervous patients we often see that, while cutaneous sensibility is still present (we refer not only to tactile sensibility but also to the other forms), it is localized more poorly and with less accuracy than is the case under normal conditions.

In the simple test of the tactile sense we may also examine, at least roughly, the power of localization if we make the patient also state where the touch is felt, or if we ask him to designate with his hand as accurately as possible the part of the skin touched. A more accurate method, much used in nervous pathology, was proposed by E. H. Weber. It consists in determining the smallest distance which must separate two simultaneous cutaneous irritants from each other, in order that they may be perceived as two locally distinct sensations. Weber has found that this distance differs very much in different parts of the body, and from this he has divided the whole surface of the skin into so-called tactile circles. As data for the examination of patients, some of the figures obtained by Weber in healthy individuals may here be given: The smallest distance at which the two points of a pair of compasses\* applied at the same time to the skin may plainly be distinguished from each other is 11 to 15 millimetres on the cheeks, 6 mm. at the tip of the nose, 22 mm. on the forehead, 1.2 mm. at the tip of the tongue, 4 to 5 mm. at

\* There are special "tactile compasses" with blunt ivory points and graduated quadrants.

the back of the tongue and on the lips, 34 mm. on the neck, 77 mm. on the upper arm, 40 mm. on the forearm, 31 mm. on the backs of the hands, 11 to 16 mm. on the backs of the fingers, 2 to 3 mm. at the tips of the fingers, 55 to 77 mm. on the back, 45 mm. on the chest, 77 mm. on the thigh, 40 mm. on the leg, 40 mm. on the instep; but these figures show certain variations in different individuals, so that they are to be regarded as only average values.

Testing the sense of locality according to Weber's method takes a great deal of time, and demands much patience and good will on the part of the patient. The influence of practice is manifested in a very remarkable way, since the perceptible difference becomes considerably less if the examinations are often repeated. On the other hand, a single examination, as in testing any form of sensibility, must not be too long protracted, for otherwise the patient may easily become fatigued, and the data obtained will be entirely contradictory. If we test the sense of locality by bringing down the two points not at the same time but one after the other, and vary it by touching the same place twice, or a different place each time, we obtain from the outset, as we have repeatedly proved, smaller numbers than if we touch the skin with the two points of the compasses at the same time. We also obtain some different values for the fineness of the sense of locality if we test the so-called sensations of motion (Leube)—that is, the distinction between a simple circumscribed touch of the skin, and a very short line drawn with a stick on the skin. In this way we can also determine whether the patient can distinguish accurately the direction of transverse and longitudinal lines.

We may also mention here the peculiar symptom termed by Fischer *polyæsthesia*, which is that certain patients, especially *ataxics*, when the skin is touched with only one point of the compasses, have a sensation as if they felt two or even more points. The cause of this remarkable anomaly of sensation is not yet adequately explained.

3. SENSE OF PRESSURE.—Since E. H. Weber's investigations we know that we estimate the difference in the intensity of our sensations of pressure, not according to the absolute, but according to the relative increase in the pressure. If, for instance, a place in the skin has a weight of nineteen grammes on it, and we perceive the first manifest increase in our sensation of pressure when a weight of one gramme is added to it; when the skin has a weight of one hundred and ninety grammes on it, we first perceive the increase of pressure not when one gramme is added, but when we add ten grammes. If this law, on more accurate testing, is not as simply proved as it seems according to the results of Weber's first investigations, still it is generally a fact that under normal conditions an increase of pressure of about one twentieth to one thirtieth of the original pressure may be plainly perceived in the different parts of the body.

Different methods and instruments, like Eulenburg's "*baræsthesiometer*," have been devised for testing accurately the sense of pressure in patients, but they have entered but little into practice on account of their elaborate character. We usually content ourselves with testing the sense of pressure by applying different weights, or coins. We must mention here that the part of the body to be tested must be fully supported, that we must also exclude sensations of temperature at the same time by putting something beneath the weights, and that we must apply the separate weights to the same place on the skin at equal intervals of time, which must not be too long after one another. There are cases where the patient does not feel even the doubling or tripling of the weights. We can easily confirm a considerable loss of the sense of pressure by means of simply varying pressure with the hand or any object, such as a pencil applied to the skin.

Partial paralyses of the sense of pressure are by no means rare. We find quite often, especially in spinal diseases, like *locomotor ataxia*, that the patient feels a

light touch on the skin, but that he can not distinguish a marked pressure at all, or only obscurely.

4. SENSE OF TEMPERATURE.—As we have already said (p. 505), we have lately been led by physiological investigations (Goldscheider, etc.) to believe more and more strongly that sensations of heat and cold are to be regarded as due to two wholly distinct functions of the cutaneous nerves. These functions are probably performed by distinct nerve terminations and nerve-fibers. From repeated personal observation we can state that pathological symptoms agree completely with this theory, for we see that changes in the temperature sense in the skin by no means affect the heat sense and the cold sense equally. It is therefore always necessary to test both forms of the temperature sense separately. We often find that while one form of temperature sense is in normal activity, the other is much altered—a pronounced partial anæsthesia to heat or cold. The affected sense may be wholly lost or merely blunted, so that hot water is felt merely as tepid, or ice as cool. If the temperature sense be lost, the application of a hot or cold object will cause only a sensation of touch, and not of temperature.

If anæsthesia to cold be present, patients often speak of having a distinct sensation of warmth when the skin is touched with a bit of ice. This symptom, which we discovered and called “perverted temperature sense,” may be explained most readily by supposing that the heat nerves are excited by the severe irritation from cold. The contrary symptom, that heat excites a distinct sensation of cold, is very much less common.

Besides the sensations of temperature we usually test also the patient's capacity to distinguish differences of temperature. Within the moderate degrees of temperature, 80° to 100° (25°–35° C.), differences of a degree Fahrenheit (0·5 C.) are easily distinguishable under normal conditions, and even half a degree (0·2 C.) can be distinguished on the face and fingers, but only about two degrees (1° C.) on the back.

Variations in the temperature sense are very common, especially in spinal diseases. The test of the sensibility to heat and cold should therefore never be omitted in testing the sensibility. It can be done with sufficient accuracy for all ordinary purposes simply by touching the skin with test-tubes filled with ice or hot water. The various thermæsthesiometers that have been devised are too complicated for practical purposes. For a hasty test it is sometimes quite serviceable to try whether the patient can distinguish warm breathing upon a given portion of the skin from cool blowing upon it.

5. SENSATION OF PAIN.—The fact is of great theoretical interest that the cutaneous sensibility for touch and pain do not always, under pathological conditions, run parallel with each other. We sometimes see that a patient does not feel a simple touch on the skin, when sticking a needle into it is immediately painful; while, on the other hand, we often find that a patient feels quite a light touch on the skin, but that the most marked irritation, like pinching or pricking it, does not excite the slightest pain, but is felt only as a simple touch, or at most as a slight pressure on it. This latter condition of sensibility, the loss of cutaneous sensibility to pain with retained tactile sensibility, is termed analgesia. Both in peripheral and in central nervous diseases analgesia is a symptom that may be quite frequently observed.

The test of sensibility to pain may be made most simply by the point of a pin, and also by pinching or severe pressure on the skin, by painful thermal irritants, by strong electrical currents, etc.

6. ELECTRO-CUTANEOUS SENSIBILITY.—The test of cutaneous sensibility by means of the electric current has been proposed from various quarters. The advantage of it is that in this way the intensity of the irritation can be very

easily and accurately graded and expressed in numbers, by the position of the cylinder in using the faradic current, or by the galvanometer in using the constant current. The faradic current is usually sufficient in testing the sensibility, and we designate it by the position of the cylinder when the first sensation is felt and the position when the first pain is felt. In general, the differences of the farado-cutaneous sensibility are not very marked. Pathological deviations are given by comparison with normal portions of the skin (testing, if possible, symmetrical parts) or with healthy people. For practical purposes, the test of electro-cutaneous sensibility is unnecessary, since its results are the same as in testing the sensibility to touch and to pain.

7. **DELAYED CONDUCTION OF SENSATION AND AFTER-SENSATIONS.**—In diseases of the spinal cord, especially in locomotor ataxia (*q. v.*) we quite frequently see a marked delay in sensation after the action of an irritant; this is also seen, but more rarely, in peripheral lesions. This delay of conduction affects chiefly the sensibility to pain. If in such a case we stick a pin into the sole of a patient's foot, several seconds elapse, even ten or twenty, it is said, before the pain is felt. As was first observed by Naunyn and E. Remak in ataxies, and as has often been confirmed since, after sticking a pin into the foot there is first a sensation of touch, and some seconds later the peculiar sensation of pain, so that the patient at once responds to the prick with "Now," and a little later with "Ow!" as an expression of pain.

This latter phenomenon has a certain relation to the abnormal after-sensations which are often observed under pathological conditions. After a simple pin-prick a feeling of burning lasts for an extraordinarily long time, or else the first pain disappears quite soon, and then a new sudden sense of pain appears several times in the same part of the skin, just as if the patient were pricked again. There is also a delayed conduction of the sensations of touch and temperature, but it is rarer, and can be made out only by the aid of more accurate methods of measuring time.

**The Sensibility of the Muscles and Joints.**—A number of sensations are classed together under the names of "muscular sense" or "muscular sensibility." They are not all wholly of the same value, and, under pathological conditions, they must be tested separately.

Ordinarily we call our power to be informed of the position of any of our limbs without the help of our eyes, and of the extent of any motion made by them, the "muscular sense." If we put a healthy person's arm into a given position when his eyes are closed, and tell him to put the other arm into the same position, he can do it with considerable accuracy. If we make passive movements in any of the joints of the extremities, a healthy person whose eyes are closed can easily and correctly state the form and direction of these movements, even if they be very slight. In nervous patients, however, this power may be diminished or lost, and we often speak of "disturbances of the muscular sense"; but we must note that the judgment as to the position of the limbs and the passive movements executed with them is not chiefly, much less exclusively, due to the sensibility of the muscles. In all probability it depends much more upon the sensibility of the articular surfaces, the ligaments and tendons, and in part even of the skin, all which tissues are relaxed or made tense in the different movements. It would therefore be more correct to speak simply of the sense of position of the limbs and the sense of passive movements instead of the muscular sense. The sense of passive movements can also be conveniently tested by describing in the air different letters or figures with the affected extremities of the patient, and requiring him to recognize them with his eyes closed. Another convenient way to test the muscular sense is to have the patient make a definite movement—pointing to or taking hold of some

object—with the eyes open, and then to make him repeat the act with the eyes shut.

We also include in the muscular sense the power of estimating the amount of work done by muscular contraction. This is the so-called "sense of power." In raising weights we can distinguish with considerable accuracy the lighter from the heavier, when the pressure on the skin is excluded as far as possible. In such cases, also, we do not deal with the absolute, but with the relative differences in weight; we can usually tell quite plainly when one fortieth of the original weight has been added or taken away. The sense of power, then, is somewhat finer than the sense of pressure. In order to exclude the latter in the test we have the patient lift the weight, suspended in a towel, with his hand or foot, but in the lower extremities it is scarcely possible to exclude entirely the co-existing sensations of pressure.

We must mention, in conclusion, that muscular contraction is in itself accompanied by a sensation, as may be proved, for example, in irritating the muscles by faradism—electro-muscular sensibility; but we have not yet found any real practical value in testing the feeling of contraction in muscles. We must state, however, that in certain forms of spasm the muscular contraction becomes so strong that it causes a decided pain, which is probably due to irritation of the sensory muscular nerves discovered by C. Sachs.

Disturbances of the muscular sense, or, to speak more correctly, disturbances in the sensibility of the deeper parts, are seen chiefly in locomotor ataxia, sometimes in paralysis of cerebral origin, and quite frequently in severe hysterical affections.

## CHAPTER II.

### ANÆSTHESIA OF THE SKIN.

**Ætiology and Pathogenesis.**—In every tract of the conducting path, which runs from the terminal apparatus of the sensory cutaneous nerves to the centers for the perception of sensation in the cerebral cortex, we may have, under pathological conditions, a break in the conduction, and, as a result of it, a complete or partial anæsthesia of the corresponding part of the skin. We speak of a peripheral, spinal, or cerebral anæsthesia, according to the place where this break in the conduction occurs. The precise anatomical course of the sensory fibers is, however, very imperfectly known, so that we can only approximately determine the location of the sensory fibers in the different portions of the nervous system.

We know this, however, of the mixed peripheral nerves before their entrance into the spinal cord, that all their sensory fibers enter the cord through the posterior roots. A part of the posterior root-fibers pass directly into the substance of the posterior gray cornua, while another part enter toward the median line into the external (in the lumbar cord, more correctly the median) portion of the posterior columns—that is, into the region of the "root-zones," or the so-called "elementary bundles of the posterior columns." Since new fibers from the posterior roots constantly enter the posterior columns of the cord, going upward from the lumbar region, the fibers which have entered in the lower portions must gradually be more and more crowded inward toward the median line. Hence it follows that the fibers entering the lumbar region, belonging to the sciatic, the crural, etc., must in the upper dorsal and cervical region occupy that internal portion of the posterior columns which is called the "columns of

Goll" (Fig. 88, G). We can not, however, state definitely at present which of the different prolongations of the posterior roots is the special path for sensory conduction. We are ourselves very much inclined to the opinion that the special sensory fibers of the posterior roots for the most part enter directly into the gray matter of the posterior cornua, and that the elementary bundles of the posterior columns—the continuation of the fibers which enter directly into the posterior columns—accordingly serve chiefly for other functions. We are led to this opinion especially by observations of quite severe disease of the columns of Goll, which occasioned no perceptible disturbance of sensation in the lower extremities during the patients' life. Disease of the posterior cornua of the gray matter, however, is always associated with disturbances of sensibility. It is not probable, according to our present experience, that there is a sensory tract in the lateral columns also in man. The fact is certainly proved, and is of importance, that all, or at least the greater part, of the sensory fibers undergo a decussation after their entrance into the spinal cord, so that the fibers from the right half of the body pass upward in the left half of the cord, and *vice versa*. We know absolutely nothing definite as to the further course of the sensory fibers through the medulla oblongata and the pons, or as to their relations to the gray matter there, but it seems to be certain that the sensory tract continues on to the cerebral hemispheres, not through the crusta, but through the tegmentum. From this point the sensory fibers pass to the internal capsule, and a number of experiments show that they lie in the posterior third of the posterior limb of the internal capsule behind the pyramidal tracts (see Fig. 64), a place where the cutaneous and muscular sensory fibers are probably near the fibers for the impressions for the special senses of vision, hearing, etc. Nothing certain is known as to the central termination of the sensory fibers. Perhaps the posterior central convolution and the portions of the parietal lobe behind it may be regarded as the special places of termination for the sensory tract. We do not know whether tracts of conduction go to the brain which are distinguished from one another according to the different forms of cutaneous sensibility.

Regarding the separate causes of anæsthesia, we see, in the first place, peripheral anæsthesia under conditions where the terminal organs of the sensory cutaneous nerves have lost their direct irritability. After chilling the skin, after the local action of ether and similar substances, after the corrosive action of acids and alkalis, carbolic acid, etc., as well as after the use of certain narcotics, such as cocaine, morphine, or atropine, we see an anæsthesia of the skin, which is due to injury of the terminal sensory organs. We may probably put the frequent anæsthesia of washerwomen in this class, for their hands and forearms are exposed all day to the action of cold, lye, etc. The anæsthesias which develop in circulatory disturbances of the skin also have the same peripheral origin, especially the "spastic anæmia" which sometimes comes in the hands and is due to a spasm of the small arteries.

We distinguish the peripheral anæsthesia of conduction, which may be produced by all forms of lesion of the nerve-trunks, from the peripheral anæsthesia in the strict sense of the term. Traumatic influences, compression from new growths, and inflammation and degeneration of the peripheral nerves, as in neuritis, are the most frequent causes of this form of anæsthesia, which is often limited to the region of distribution of one or more definite nerves.

Spinal anæsthesia is very often seen in the different diseases of the spinal cord, most frequently in locomotor ataxia, because this, as we shall see later, attacks chiefly the posterior roots, the posterior columns, and the posterior cornua of the cord; but spinal anæsthesia is not infrequent in diffuse acute and chronic inflammation of the cord and in compression and new growths. As a rule, it is bilateral,

para-anæsthesia. The hypothesis advanced by Schiff is quite widespread, but is by no means certainly proven, that the gray matter of the cord conducts chiefly the impressions of pain, and the white matter of the posterior columns the sensations of touch. According to this, in spinal analgesia we must assume chiefly an impairment of the gray matter.

Cerebral anæsthesia is seen especially in hæmorrhages, foci of softening, and tumors, which affect the posterior portion of the internal capsule: but of course the break may occur in any other part of the tract of sensory conduction in the brain. If the cerebral anæsthesia, as is often the case, affects the half of the body opposite the lesion in the brain, we term it hemianæsthesia. Very extensive cerebral anæsthesia of a marked degree is quite frequently found in severe cases of hysteria. We also know that the anæsthetic action of the remedies termed anæsthetics and narcotics, such as chloroform, morphine, ether, alcohol, bromide of potassium, etc., must be explained by their influence on the central nervous system.

Among other ætiological factors we must also mention that we sometimes see more or less extensive anæsthesia as a result of acute diseases, such as typhoid, diphtheria, and other acute infectious diseases, the origin of the anæsthesia, whether peripheral or spinal, being as yet uncertain. Peculiar insular and, rarely, diffuse anæsthesia, showing itself chiefly on the backs of the hands and the chest, is found in the secondary stages of syphilis, according to Fournier; but there has been no further confirmation of this statement so far as we know.

**Symptoms.**—In many cases the patient himself notices the existence of anæsthesia. He finds that in certain parts of the body he no longer feels the pressure of his clothing or the bedclothes in the usual way. Anæsthesia of the hands is soonest noticed, because this can affect the patient's occupation in diverse ways, so that, for example, he readily lets fine objects, such as needles, drop from his hands. In other cases, of course, the anæsthesia is first found on a physical examination, which alone can give definite disclosures as to the extent and intensity of the affection. For this purpose the skin must be carefully examined by the methods given in the preceding chapter. It is worthy of note that hysterical anæsthesia especially, even if it be very marked and extensive, may often be wholly overlooked by the patients themselves.

Anæsthesia is very often combined with abnormal subjective sensations, paræsthesia, in the affected portions of the skin. The patient has a feeling there of "numbness," or a "furry feeling," or complains of prickling or formication. The anæsthetic parts may even be the seat of very decided pain (*anæsthesia dolorosa*), if there is abnormal irritation of the sensory nerves from the break in the conduction toward the center. The most diverse forms of anomalies of motility and of the reflexes, and vaso-motor disturbances, may of course be present in addition to the anæsthesia. Special mention must be made of trophic disturbances which are often seen in anæsthetic regions. We shall return to the peculiar characteristics of these repeatedly in subsequent chapters; therefore we need state here only that the trophic disturbances have nothing to do with the anæsthesia itself. They depend either upon a co-existing lesion of special trophic or vaso-motor nerves, or upon the fact that external irritants, which act upon any anæsthetic portion of the skin, are not felt normally by the patient, and hence are often not avoided. In anæsthetic regions we often find large external wounds, burns, bed-sores, inflammations, etc., which were not noticed by the patient in time to prevent them, and hence they often attain an unusual extent.

Voluntary motion is not disturbed by anæsthesia in itself, of however great a degree, as long as the motions can be controlled by the eyes, but finer movements are often considerably impaired by cutaneous anæsthesia; thus patients with

diminished sensibility in the fingers can usually no longer sew, because they lose the needle every minute. With the eyes shut, however, the motions of the anæsthetic parts become very uncertain, both in anæsthesia of the skin and of the deeper parts, the muscles and joints, since then the patient loses, to a great degree, his power of judging of the extent and of the precise direction of his movements. Very extensive anæsthesia of the skin, associated at the same time with anæsthesia of the organs of special sense, is sometimes not without influence upon consciousness. We have for several years had under observation a very remarkable case of total anæsthesia of the whole body associated with unilateral blindness and deafness. If we entirely exclude this patient from all external impressions of sense by closing his still serviceable eye and ear, we can at once in this way put him into a deep sleep!

We can not here go into details of the different forms and distributions of anæsthesia, since they will be spoken of under the different diseases which lie at the basis of the anæsthesia. The course, the duration, and the prognosis of the affection depend, in the first place, of course, upon the form of the primary disease. We will add here merely a few remarks upon anæsthesia of one nerve, namely, anæsthesia in the distribution of the trigeminus.

**Anæsthesia of the trigeminus** is observed in tumors, syphilitic new growths, chronic inflammations, and analogous processes at the base of the skull, which compress the trunk, the Gasserian ganglion, or one of the three branches of the trigeminus, or directly involve the nerves. Traumatic lesions of the trigeminus are also not very uncommon. The distribution of the anæsthesia, according as the affection involves the whole trigeminus, or only one branch of it, may be seen in Figs. 57 and 58. In total anæsthesia of the trigeminus, the conjunctiva and

cornea, the mucous membrane of the nose, the cavity of the mouth, and the tongue are anæsthetic on the affected side. Hence we often find ulcers on the tongue and the mucous membrane, which come from being bitten. The "neuro-paralytic ophthalmia" not infrequently seen in anæsthesia of the trigeminus is of special interest, and has been much studied by physicians and physiologists. This

is an ulcerative keratitis, almost always beginning in the lower segment of the cornea, and sometimes passing over into a purulent inflammation of the whole eyeball. This affection is regarded in many quarters as an immediate result of the disturbance of special "trophic" functions, but, after careful experiments (Senffleben), it seems most probable that external traumatic influences always occasion the first trouble, and render the intrusion of inflammatory agents possible. It is still uncertain whether we must also assume a specially diminished power of resistance on the part of the tissues as a result of the nervous lesion.

The skin of the face is often somewhat bloated in anaesthesia of the trigeminus, and it is cyanotic and feels cool. The reflexes are lost in peripheral anaesthesia, and the lachrymal secretion is diminished. The taste is almost always decidedly diminished on the anterior two thirds of the tongue on the affected side, the territory supplied by the lingual nerve.

**Treatment.**—Since anaesthesia in most cases is only a symptom, treatment, of course, must always first be directed against the underlying disease. Therefore we will mention here only those measures which are to be used symptomatically

\* Henle's nomenclature of the peripheral nerves has been adopted.—TRANS.

against anæsthesia, and which must be tried when the special cause can not be discovered, or when it is inaccessible to treatment.

The chief remedy is, without doubt, the electric current. We treat the anæsthetic part of the skin with the faradic current, using ordinary electrodes, or, better still, the wire brush, or with the galvanic current, stroking the skin slowly back and forth with the cathode for three or four minutes. Sometimes we can see a result immediately after the sitting. Hysterical anæsthesia may often be removed in this way in a very short time.

Besides electricity we usually prescribe embrocations to irritate the skin, such as spirits of camphor, spirits of mustard, formic acid, spirits of thyme, etc., and also baths, and cold or hot local douches, combined with rubbing the skin. The action of internal remedies is extremely doubtful. *Nux vomica* or strychnine, tincture of valerian, etc., have been recommended.

It is very important to protect the anæsthetic part against external injuries. In anæsthesia of the trigeminus, particularly, we guard the eye as far as possible from the development of a neuro-paralytic keratitis, by a carefully applied occlusive bandage.
